Method of employing the Carotid Compressor.	213		
An Immobilizing Dressing for treating Fracture of the Surgical Neck of the Humerus.	215		

Lectures and Addresses.

A MEMOIR OF

DR. JAMES MARION SIMS.*

By THOMAS ADDIS EMMET, M. D.

JAMES MARION SIMS sprang from the Scotch-Irish stock who settled up the frontiers of North Carolina and eastern Tennessee.

Many years ago, while investigating for my pleasure a point of local history, I was struck with the frequent mention of the name of Sims in this section of country, and, on inquiry, learned from the doctor that his family first settled on the frontier, and, after the Revolution, his grandparents, I believe, returned to the "settlements."

In Lancaster District, S. C., Dr. Sims was born, January 25, 1813. Of his boyhood I have heard him state that he was a good boy, but a dull one at school—scarcely a just criticism, I think. He may have been wanting in application, but, if the man was any indication of the boy, there could have been no time of his life when he would have been dull in any sense of the term. In 1832 he closed his academic studies, and received the degree of Bachelor of Arts from the College of South Carolina, at Columbia. He began the study of medicine in the office of Dr. B. C. Jones, a practitioner of Lancaster, and his first course of lectures was taken in the Medical College of Charleston, S. C. The following years he received his degree from the Jefferson Medical College, Philadelphia.

He returned to the place of his birth to commence the practice of his profession, but, not receiving a sufficient encouragement from those who had known him from childhood, he removed to Mount Meiggs, a settlement a few miles from Montgomery, in the State of Alabama. In 1836 he married Miss Eliza T. Jones, the daughter of his old preceptor, and remained a year longer at Mount Meiggs; then he practiced about three years in Macon County, and finally settled at Montgomery about 1840.

He seemed to have made but little progress during the first year; but shortly after this time he became interested in the operation for strabismus, which had been recently devised by Dieffenbach, and, having been able to put it successfully in practice, together with a remarkable cure he effected in a case of club-foot, he gained a surgical practice which in a few years became one of the largest in the State. His first contribution to medical literature was a paper on "Trismus Nascentium," which was published in the "American Journal of the Medical Sciences" in 1846.

In July, 1845, Dr. Sims was called to a patient who had been thrown from a carriage and was suffering from a retroversion in consequence of the accident. During his effort to restore the uterus he placed her in what is now termed the "knee-and-chest position"; but, finding that he could not fully reach the womb with the index-finger alone, he

introduced the second one, with the immediate effect that he could then neither touch the cervix nor the walls of the vagina, and, to his surprise, she announced that she was entirely relieved. To this accident, and to the dilatation of the vagina when placed in a certain position after retracting the perinæum with the fingers, we are indebted for the speculum bearing his name, and for the first operation by him in a case of vesico-vaginal fistula.

In the anniversary discourse delivered by Dr. Sims before this body on the 18th of November, 1857, the subject being "Silver Sutures in Surgery," he had given a most graphic description of the difficulties overcome, and of the many disappointments he experienced during some four or five years before he cured his first case. This success was gained June 21, 1849, by the use of silver wire, after thirty failures, in this individual alone, to close the opening by means of silk.

Shortly after this triumph, and with a most prosperous future before him, his health failed, and he became a sufferer from chronic diarrhœa. It was a type of the disease which seemed particularly fatal at that time, and equally so if contracted in the Southern States or in Mexico, from which country so many of the troops were then returning home after the war to die from this malady. For two years or more Dr. Sims sought to regain his health by a change of climate, and with any improvement would return to his business, but finally was obliged to relinquish it entirely.

In October, 1851, while in Philadelphia, and when in the last extremity of the disease, as he supposed, he dictated a paper on "Vesico-Vaginal Fistula," which embodied his experience up to that date, and this was published in the "American Journal of the Medical Sciences" for January, 1852.

Dr. Sims had observed, during a number of visits to New York, that the only improvement in his health occurred while he remained in the city. Early in the autumn of 1853 he decided to settle permanently in New York, and in November of that year I first made his acquaintance. With a growing family, and now in straitened circumstances, it was necessary to select a house at a moderate rent, and on the outskirts of the city. This building, which had just been erected, was situated in Madison Avenue, between Twenty-eighth and Twenty-ninth Streets. To the best of my recollection it stood alone, with no first-class dwelling-house nearer than Twenty-third Street, and in full view of the East River. I happened to be walking with a mutual friend, and had never heard of Dr. Sims before. His sign suggested the visit, and I had the choice of going in or of standing on the street. I was introduced, and then little thought how close our future relations were to be, or that this man, so emaciated and apparently at death's door, was about to enter upon a career which was to be of world-wide renown. I could then as little realize the future as I could have foreseen the growth of the city from its then limits to its present bounds.

In October, 1853, Dr. Sims received from Dr. Mott his first patient in New York—a small vesico-vaginal fistula, where the neck of the uterus was found in the bladder, a

* Read before the New York Academy of Medicine, January 3, 1884.

condition then regarded as unique. But this is now well known to be a common result from retroversion, when produced by inflammatory shortening of both broad ligaments, and where, the slough having taken place directly in front of the cervix, it easily passed into the bladder, and, with the cicatrization afterward, the opening became reduced in size. Dr. Sims successfully closed this fistula, but left the neck of the uterus in the bladder, and reported the case in the first volume of the "*American Medical Monthly*," published in this city, February, 1854.

Soon after his arrival, he formed the acquaintance of Dr. Barker, Dr. Mott, Dr. Francis, Dr. Stevens, and others, and it was thought advisable that Dr. Sims should deliver an address to the profession setting forth the necessity for a woman's hospital, where vesico-vaginal fistula and a few of the injuries of childbirth might be treated. Little thought was given at that time to the need for any special place or treatment for the diseases of women. I well recollect a statement made by Dr. David M. Reese, now many years dead, but at that time a prominent general practitioner and a fair surgeon, that it was easy to apply the nitrate of silver through a cylindrical speculum to any case of ulceration; an infusion of red-oak bark could be given for a leucorrhœa, and, if a prolapse existed, any one could put in a Meigs's ring or Physick's spherical pessary. He laughed at the idea of the necessity for a woman's hospital, and thought it impossible to find enough women sick enough to fill it. What a contrast between such a statement and our knowledge of to-day! This gentleman felt satisfied that he had mastered the whole subject in treating these three conditions, which, as symptoms of different pathological changes, would not to-day convey alone to any one a knowledge of the true lesion. This appeal was made by Dr. Sims at the Stuyvesant Institute, in Broadway opposite Bond Street. It was judiciously arranged in regard to the speakers that it should prove a success, and the indorsement there given him by the profession was the beginning. I attended this meeting, which was held May 18, 1854, and from that time to the present I have been familiar with every circumstance connected with the development of the Woman's Hospital. In fact, if the history of this institution is ever to be written, it must be done from the information which I alone can furnish, for no one is now living who could do so much.

As Dr. Sims's career was so closely identified with the early history of the Woman's Hospital, it is necessary that I should make some reference to those who aided him in the good work. All credit must be given Dr. Sims for the conception of the Woman's Hospital, as well as for the power of impressing others with the necessity of its existence, and his name must be for ever identified with the institution as the originator. But he had none of the qualifications of an organizer, and his conception would not have even reached a realization without the aid of others. Every one, I believe, connected with the movement has received more or less credit from some source, with a single exception. I entered upon this subject with the object of recording what I know to be true, and had written out my recollections without the knowledge of the gentleman to a point where it was necessary then to consult him in regard to certain data which he

could alone furnish. I refer to our President, and believe that to Dr. Fordyce Barker, more than to any other individual, we are indebted for the early organization of the Woman's Hospital. Dr. Barker was about the first acquaintance made by Dr. Sims in the medical profession after settling in this city, and it was through him he became acquainted with Dr. Mott, Dr. Francis, Dr. Stevens, and others. Dr. Barker took an active part in the meeting, and just after, in the June number of the "*American Medical Monthly*," wrote an editorial article on Dr. Sims's claims, entitled "*Young America vs. British Surgery*." The points are well taken against a surgeon of St. Mary's Hospital, London, who had reported two cases of vesico-vaginal fistula, operated on by him, in which he used Sims's position, speculum, silver sutures, and self-retaining catheter without the slightest credit being given to any one but himself. The editor's advice—"Fie, Mr. Bull, set a better example before your young men; if you get an idea from young America, have the manliness to say so"—was excellent, but it was not followed altogether, since we see sometimes, even at the present day, the force of a bad example.

At the first meeting held to form an organization, Dr. Barker suggested, with a single exception, the names of all the ladies who constituted the first board of managers of the Woman's Hospital Association. He was at the time the family physician to all, with the single exception, and it was through his personal influence that these ladies were induced to assume the responsibility. Mrs. Fordyce Barker was the first secretary of this board, and discharged the duties for two years after its organization, in a position which, even under more favorable circumstances, would have been a thankless one. Soon after the hospital had gone into operation, Dr. Barker was able to render further service, while twice president of the State Medical Society, at Albany, and to prepare the way for obtaining from the Legislature the charter of the institution now known as the Woman's Hospital of the State of New York.

Dr. Francis, who knew every one, was a host in himself, and it was his special province to prepare, from time to time, the necessary appeals to the public and to the Legislature for obtaining the charter. Mr. Beekman, Mr. Benedict, and others, who formed the Board of Governors of the proposed State Hospital, and who were nearly all governors at the same time of the New York Hospital, obtained from the city a grant of the land for the site of the present institution, then a part of an old Potter's Field from which over thirty thousand bodies were removed. Through the efforts chiefly of Mrs. T. C. Doremus, a house was obtained in Madison Avenue, and her husband, I believe, became security for the rent. How much was due to the individual efforts of this noble woman will never be known; she kept her own counsel, but served the institution, even to the day of her death, with a most remarkable singleness of purpose. In brief, I have given an account of the chief movers in organizing this undertaking, a work which was physically impossible for a single individual to have performed. Dr. Sims, however, did accomplish even a greater work in his own legitimate sphere, and this I will endeavor to trace.

The Woman's Hospital Association opened its doors

May 4, 1855, and Mary Smith, the first patient received, suffered from a vesico-vaginal fistula, and had arrived from Ireland but a short time before.* She proved to be one of the worst cases ever admitted to the institution. To keep the fundus of the bladder from prolapsing through the vagina, some almshouse physician of her district had, before she left, introduced into the cavity a wooden float from a seine, in size not less than a closed fist, and this had become thoroughly coated with a phosphatic deposit. This miserable object was operated on over thirty times, almost always on the knees and chest, each operation lasting from two to three hours, without ever taking an anæsthetic, and she suffered during a period of nearly five years before even partial retention was gained. For a long time she was the "show-case" for demonstrating the mode of operating. After the opening had been closed, so much traction was then exerted on the urethra that more or less urine escaped while in the upright position, and in time, from this source of irritation, a stone was at length formed in the bladder. Against my advice, some years ago, the urethra was dilated for the removal of the stone, and the neck of the bladder was lacerated, with incontinence afterward, so that the first patient admitted to the hospital is still living in suffering, in poverty, and incurable.

The consulting board consisted at first of Dr. Francis, Dr. Mott, and Dr. Stevens; Dr. Green and Dr. Delafield were subsequently added. These gentlemen were all eminent in their different branches of the profession, but were necessarily conservative in so new a field. Dr. Sims early evinced a boldness and desire to enter upon an investigation as to how far abdominal surgery could be made safe through the use of silver wire, and the difficulties would have been soon overcome if he could have had a portion of the responsibility shared by his consulting board. I was present, as a listener, at one of the early consultations, when Dr. Sims proposed to open the abdomen for the removal of a long pedunculated fibroid—an operation which few would hesitate in doing to-day. Dr. Francis and Dr. Mott were at first disposed to yield to Dr. Sims, until Dr. Stevens entered a protest. He had no opinion to express, he said, in regard to Dr. Sims's views; they might be all right, but he felt, if Dr. Sims should succeed by chance, that every young surgeon in the land would be ripping open the bellies of the young women to ascertain if they had such growths to be removed, and he would oppose such an operation simply on the ground of humanity. Dr. Sims was not able to carry out his wishes in regard to several cases of ovarian tumor, and it was not until about 1860 that he felt his position sufficiently established to perform, on his own responsibility, his first ovariectomy.

Dr. Sims visited Europe early in July, 1861; he remained absent until the middle of January, 1862, and, on August 31, 1862, he left New York with his family to reside abroad. During his service of six years and nine months in charge of the Woman's Hospital Association, his only

* I will mention the fact in passing that, up to ten years ago, exactly fifty-eight per cent. of all the patients with vesico-vaginal fistula which had been treated were admitted, like this woman, directly from the different almshouses of Great Britain and from the Continent.

contribution to medical literature was, I believe, the Address "On the Use of Silver Sutures," and he seemed to have taken no active part in the proceedings of the medical societies. He was, however, most actively employed, and, with a gradual improvement in his health, he developed a remarkable tolerance, as it were, for hard work. He was perfecting and devising new instruments, studying modes of exploration, and planning different surgical procedures, all in a field too new to find any precedent to aid him in the experience of others. In the midst of this busy life the civil war came on and cut short this continued strain to both mind and body. It proved, however, a fortunate circumstance for him and for his subsequent reputation. His residence in Europe gave him the leisure, and it became even a necessity, to perfect and utilize much which would otherwise have been lost.

Dr. Sims was by nature a surgeon, and one of the most dexterous operators I ever witnessed. He was bold and self-reliant, never at a loss, and his ingenuity was unequalled. He was in no sense a plodder, for his mind and body were always too restless and active. He was so fertile in resource when I first knew him that he perfected scarcely a tithe of the brilliant conceptions passing constantly through his mind, and it was impossible to see him perform the most simple operation without learning something new. It may be held that, for want of further hospital advantages for study, Dr. Sims's creative power culminated when he left the Woman's Hospital. As his surgical reputation will be hereafter always intimately associated with what he had perfected before that time, I will briefly give a synopsis of his work:

In perfecting the preparatory treatment, in devising the needed instruments, and by overcoming the difficulties in operating for vesico-vaginal fistula, Dr. Sims exhibited a degree of pertinacity which in after-life he was unable to devote to the development of any other special object. Notwithstanding a similar speculum has been taken from the ruins of Pompeii, and a like instrument, as a retractor, had been used by Metzler, in Germany, before the present instrument had been devised by Dr. Sims, the credit in the future must belong to him alone. The metallic suture had been used by Dr. Le Vert, of Mobile, Ala., before 1828, and by Mr. Gosset, of London, in 1834; the clamp suture had been already employed, with the "knee-and-chest position," and with other details now in use; while vesico-vaginal fistulæ had been successfully closed in different parts of the world before Dr. Sims began to study his profession. "Yet with all," as I have elsewhere stated, "were we assured of the fact that Dr. Sims was as familiar as we are at the present time with what had been accomplished before his day, it should not lessen the credit due him. What had been done fell on barren soil, bore no fruit, was not appreciated, and was destined to be forgotten. From Dr. Sims's hand the operation was accepted by the profession; it was immediately put into successful practice, and to the present day it has not been materially modified for the better in either its principles or its mode of execution."

I hold in my hand a speculum which belonged to Dr. Sims, and is, I believe, the first perfected one from the hands

of the instrument-maker. From the beginning of time to the present I believe that the human race has not been benefited to the same extent, and within a like period, by the introduction of any other surgical instrument. Those who do not fully appreciate the value of the speculum itself have been benefited indirectly to an extent they little realize, for the instrument, in the hands of others, has probably advanced the knowledge of the diseases of woman to a point which could not have been reached for a hundred years or more without it. Those who come upon the field to-day can not realize what has been accomplished, or the fact that the study of gynecology now covers a more extended field than the whole knowledge of medicine did forty years ago. The advance made in this branch of surgery has, through this instrument, become especially identified with this country, where it has been chiefly employed.

To Dr. Sims we are indebted for the technique of the examination. He first suggested the advantage of employing the left hand and the use of conjoined manipulation. The advantages of "Sims's position" on the left side, I believe, can not be questioned. In addition to the speculum, we are indebted to him for the depressor, the flexible copper sound, the tenaculum now in use, and the elevator. He first introduced the use of glycerin and taught its advantages. He perfected the making of sponge-tents, and first understood how to apply a tampon, an operation which can never be performed properly without the use of his speculum. The stick, with the screw at the end, for removing the cotton, is his, and he introduced the probang sponge-holders now in use. He first had the block-tin pessary made, and from his hands I have seen formed, over twenty-five years ago, every shape and modification which has since been devised. Dr. Sims was the first to abandon that barbarous appliance, the quill suture, and to simplify the operation for closure of a lacerated perineum by the use of the interrupted silver suture. He gave us the operation on the anterior wall of the vagina for the cure of procidentia and prolapse. And, notwithstanding it fails when used alone for keeping up the uterus, it is perfect if employed with the object of holding the uterus at a distal point from the pubes, while the needed support is obtained by the proper operation on the posterior wall. I could indefinitely extend the record of operations devised, but not carried out, and of instruments never perfected. There were certain operations practiced by him which will go into disuse, and some of his teachings will not stand the test of time. But this is not to his discredit, for few men will ever have more to live after them. Crowded into a few years as were all of Dr. Sims's opportunities for clinical study in hospital practice, it is most remarkable that from the brain and hands of one individual so much should have emanated and so perfected that the human race will be benefited long after the source has been forgotten.

I can not attempt to trace his career abroad, or give more than a general outline of this period of his life. He visited the chief cities of Europe, but resided for the greater portion of the time in Paris and London. He received marked attention everywhere, and at once entered upon a large and extended practice. In 1865, while residing in London, he

wrote his "Clinical Notes on Uterine Surgery," and states in his preface: "It is simply a voice from the Woman's Hospital, which, in all probability, would never have been heard if I had remained at home." This book was translated into the French and German languages, and issued at the same time with the English edition, which was afterward reprinted in this country. The work attracted a great deal of interest, at the time of its issue, as a very remarkable one. I believe few medical works of its size were ever issued containing so much original and, I may say, suggestive matter. It was so far imperfect, or rather fragmentary, in character as to treat of a very limited range of diseases. But its publication was the turning point of modern gynecology, or, more strictly speaking, American gynecology, of which he may be justly termed the father. For the critic, however, this work had many weak points, as it was not a systematic production, and was never intended to be one. He had also advanced, with his enthusiastic zeal, certain views which were theoretical and would not stand the test of clinical experience. Withal, in the history of some cases there was a want of accuracy, as he had not access to the hospital records, and had to trust to his memory. It is now a source of no little regret to those who fully appreciated the true value of the book that Dr. Sims did not revise it and produce a systematic work embodying his matured experience, of which so much has now been lost.

Several years after the departure of Dr. Sims for Europe a sufficient sum of money, by subscription, was collected through the personal efforts of Mr. A. R. Wetmore, the late Vice-President of the Board of Governors, and the cornerstone of what is termed, in recognition of this service, the Wetmore Pavilion of the Woman's Hospital was laid May 23, 1866. This building was completed on the 12th of October, 1867, and was then occupied by patients for the first time. The Woman's Hospital Association, which had consisted of a Board of Lady Managers, now ceased to exist as a distinct corporation, and became blended with the one in charge of the Woman's Hospital of the State of New York. After the hospital had been in full operation for a year or more, Dr. Sims returned to New York for a few months, having been absent some six years. In 1868 he was appointed one of the governors of the Woman's Hospital, and had conferred on him the honorary title of Senior Consulting Surgeon. He contributed, in 1869, to the eighth volume of the "New York Medical Journal," a paper "On the Microscope as an Aid in the Diagnosis and Treatment of Sterility," and it had been read by him before the Medical Society of the County of New York, December 7, 1868.

His family remained abroad and he was only a portion of each year in this country until after the Franco-Prussian War. While in Paris, the "Anglo-American Ambulance Corps" was organized, August 27, 1870, by eight American and the same number of English surgeons, with Dr. Sims as surgeon-in-chief. He was the eldest surgeon who left Paris for this duty, and, arriving just at the commencement of the battle of Sedan, he was placed in charge of a military hospital containing four hundred beds, and served as chief for a month or more. Shortly after rendering this service he returned with his family to New York.

Dr. Sims was appointed, January 9, 1872, a member of the Board of Surgeons to the Woman's Hospital, but the new organization was not fully completed, and he did not enter regularly upon his duties until the following 1st of May. On the 1st of December, 1874, Dr. Sims resigned, thus terminating his brief service as surgeon to the Woman's Hospital, and he had no further connection with the institution until shortly before his death, when he became one of the Consulting Board.

In the "New York Medical Journal," December, 1872, and April, 1873, he contributed an article on ovariectomy, in which he advocated free drainage, through Douglas's cul-de-sac, of the peritoneal cavity. Before the New York State Medical Society, Albany, February 6, 1874, he read a paper on "Intra-Uterine Fibroids," and this was published also in the "New York Medical Journal," April, 1874. Soon after, in the "History of the Discovery of Anaesthesia," he supported the claims of Dr. C. W. Long, of Athens, Ga., to the credit of having performed the first surgical operation with the patient under the effects of an anæsthetic. A few other articles in the various journals, of minor importance, and his addresses as presiding officer of several societies, would embrace all his contributions to medical science.

Dr. Sims was elected President of the American Medical Association, and presided at the meeting held in Philadelphia, 1876. He was president of the American Gynecological Society at its meeting in Cincinnati, Ohio, 1880, and was one of the founders of the society. In recognition of the service rendered by Dr. Sims to medical science he was the recipient of many honors from different governments of Europe, and probably few men in the profession ever received an equal number of honorary distinctions from various societies in different parts of the world. One of the last honors conferred was that of Doctor of Laws from the Jefferson University, Canonsburg, Penn., with which his Alma Mater, the Jefferson Medical College, of Philadelphia, is connected.

Dr. Sims came of a long-lived family, and was remarkable for his temperate and simple mode of life. He had none of the "small vices," and every habit of life was made conducive to maintaining his health. He preserved to a late period a youthful figure, with a degree of elasticity and activity of body seldom enjoyed even in middle life. He thus had the promise of a long life, and he always said, as he expressed it, that he was "good for ninety." About two years ago, after a long and fatiguing operation, he was seized with an attack of pneumonia, and his life, day by day hanging in the balance, was only saved by the unremitting care of his medical attendants. He never fully recovered from this attack, and it necessitated the spending of the following winter in Florida, and the last in the south of Europe. During the warm weather he improved, and, on his return to New York in August last, it was thought that he had regained his former vigor and strength. To the day of his death he was actively engaged in the duties of his profession, and it is stated that he had visited a patient with his son just before retiring. During the night he was restless, and wrote for a time in bed, as was his custom. Sud-

denly his heart came to a standstill, and he died, without a struggle, November 13, 1883.

Mrs. Sims has survived her husband. A sketch of him would be incomplete without some notice of her, who continued as the sweetheart of his youth and help-mate through a long life. I have heard him state that he could have accomplished nothing without the aid and advice of his wife. She certainly devoted her life to him, and I never saw a person more dependent on another than he was on her. When I first knew them, and he was in bad health, she always prepared with her own hands every particle of food he needed. She watched over him with a singleness of purpose only equaled in the care of a mother for her offspring. For his impulsive nature her placid disposition was as essential as the fly-wheel to an engine, and he has said that through his whole life he never had to regret following her advice.

My relations with Dr. Sims in early professional life were as close as that of a son could be. Later on, from circumstances over which I had no control, we did not meet for years. During the summer of 1882, and in London, while I was closely watching the steps of an operation, some one came into the room breathing quickly, as if he had been ascending the stairs. For a second of time I was annoyed as this gentleman sided up so close to me, but his hand passed into mine as he whispered, with a familiar voice, "How are you, old Emmet?" and I shook Dr. Sims by the hand for the last time.

Original Communications.

THE RELATIONS OF A PHYSICIAN TO THE COMMONWEALTH.*

By E. C. HARWOOD, M. D.

MR. PRESIDENT AND FELLOWS: You have all been officially notified that I would speak to you this evening on "The Relations of a Physician to the Commonwealth." Heretofore you have listened to able men on a variety of topics, covering almost everything in the domain of medicine and surgery. It was for this reason that I diverged from the beaten path and assumed to give you something new and original, at least in the title; but I must assure you that I do not claim originality in the text, for it will be mostly statutory.

There are prescribed rules which must be observed to enable one to become a member of the learned professions. They are founded in good sense and are meant for the common good. A man rarely takes upon himself the responsible duty of expounding the Scriptures, and of bringing home to the human heart, buried and estranged as it sometimes may be by the cares of the world, an awakening sense of moral right and wrong, unless he carries unquestionable credentials of his fitness for his vocation. It is not enough

* Read before the Northwestern Medical and Surgical Society at its thirteenth annual meeting, December 19, 1883.

that he is fit, but those who listen should feel assured that he is so. It is wisely and properly required that there should be an authority somewhere enabled to grant the necessary credentials; the schools of divinity and the learned who preside there have the authority to grant them.

In the administration of justice there are also prescribed rules which must be observed to qualify one to practice law. A course of collegiate study, or an equivalent, and a number of years devoted to the science of the law and collateral studies are properly held to be indispensable. When a student is qualified to be received into the courts he takes a solemn oath, prescribed by a law of the commonwealth, "that he will do no falsehood, nor consent to the doing of any in court; that he will not willingly pursue or promote any false, groundless, or unlawful suit; that he will delay no man for lucre or malice; that he will conduct himself with all good fidelity, as well to the courts as his clients." *

He thus becomes an officer of the courts and is recorded as such, and is liable to be stricken from the record and disqualified to appear as counsel if he proves to be unworthy. All these provisions are of the greatest importance to the community, since it is from this class of men that the judges of constitutional law, of the rights of the people to property, liberty, character, and life, are selected.

In the medical profession the same probation is required. Certainly no one should be trusted with the serious responsibility of attempting to arrest the ravages of disease, or of inserting his professional instruments among the veins, arteries, muscles, and nerves of the human frame, who is not prepared, by a course of study, observation, and experience, to make his previous plan with science, and to carry it into effect with skill. It is for the common interest of society to discountenance unfounded pretension, and to call upon and confide in those who are certified by competent judges to be trustworthy and honorable men.

The practice of medicine and surgery was regulated by the Legislature of this State so far back as 1760—now one hundred and twenty-three years ago—when, on the 10th of June, an act was passed especially designated for the city of New York.

In 1767 the first general regulations for the whole State were adopted, providing for the licensing of physicians and surgeons. By this act the chancellor, a judge of the Supreme Court or Common Pleas, or a master in Chancery, was authorized to license physicians and surgeons to practice on receiving evidence of their having studied two years.

In April, 1801, this act was revised (with many alterations), and was subsequently amended in 1803, 1806, 1818, 1819, 1827, and 1830.

The act of 1806 provided that any person who should commence practice after the first day of September, then next, without being duly licensed, should for ever thereafter

be disqualified from collecting any debt or debts incurred by such practice. It further made the unauthorized practice of physic and surgery a misdemeanor, punishable by fine or imprisonment, or both. These provisions were repeated in the revised law of 1813.

In April, 1813, an act was passed incorporating medical societies throughout the State, and providing for their organization and defining their powers.

Afterward (1827) the powers and duties of medical societies were more clearly defined, and in April, 1830, an act was passed repealing the clause of the act of 1806, above referred to, and the unauthorized practice of physic and surgery was punished by fine only, instead of by fine or imprisonment, or by both, as provided by the laws of 1806.

The second section of this act is as follows: "Every person not authorized by law who shall practice physic or surgery within this State shall, for every offense of which he may be duly convicted, forfeit and pay a sum not exceeding twenty-five dollars, to be recovered, with cost of suit, before any justice of the peace of the county where such penalty shall be incurred, by any person who will prosecute for the same; but the provisions of this section shall not be deemed, and taken to extend to, or debar any person from using or applying for the benefit of any sick person any roots, barks, or herbs the growth or produce of the United States."

The offense, therefore, of practicing without license was changed from that of a misdemeanor, punishable by fine or imprisonment, or both, to one punishable simply by fine. The last clause of this act is worthy of notice, as it was the first occasion on which any mention was made of particular remedies. This act allowed the sale of herbs, roots, and barks produced in the United States for the benefit of any sick person, thus legalizing quackery.

It would seem that the legalization of quackery by this statute was found to work injury, as, in 1834, this act was amended so that only such persons as should, without fee or reward, use or apply roots, barks, or herbs the product of the United States, were exempted from the penalty of the act of 1830. The next year it was deemed advisable to strike out the exemption clause and thus revive the law of 1830, by which the unauthorized practice of physic or surgery was punished by a fine. Some years then elapsed during which the laws above mentioned were in force, and no material alteration or change was effected under these laws. All physicians and surgeons were required to be duly licensed.

By an act passed May 6, 1844, the law of 1830 was repealed, and it was enacted:

SECTION 3. No person shall be liable to any criminal prosecution or indictment for practicing physic or surgery without license, except in case of malpractice, gross ignorance, or immoral conduct in such practice.

SEC. 4. All and every person, not being a licensed physician, who shall practice, or attempt to practice, physic or surgery, or who shall prescribe for or administer medicines or specifics to or for the sick, shall be liable for damages in case of malpractice as if such persons were duly licensed to practice physic or surgery.

SEC. 5. Any person, not being a licensed physician, who shall

* The oath varies somewhat in different States, but is essentially the same in all. The following is the form in this State:

"You do solemnly swear to support the Constitution of the United States and the Constitution of the State of New York, and to faithfully perform the duties of an attorney and counselor-at-law in the several courts throughout this State to the best of your ability, so help you God."

practice, or profess to practice, physic or surgery, or shall prescribe medicines or specifics for the sick, and shall, in any court having cognizance thereof, be convicted of gross ignorance, malpractice, or immoral conduct, shall be deemed guilty of a misdemeanor, and liable to a fine of not less than fifty dollars nor not exceeding one hundred dollars, or imprisonment in the county jail not less than one month nor exceeding twelve months, or both, in the discretion of the Court.

Thus, there was no longer any occasion for a license, and any person was permitted to practice medicine or surgery, being only responsible for gross ignorance, malpractice, or immoral conduct in such practice.

This act did not establish any standard of knowledge or fitness to practice, and, as it failed to define what degree of ignorance constituted grossness, it seems that this provision was almost useless; examinations and degrees were no longer necessary, and, consequently, any person who chose could not only practice, but could collect his fees for services on *quantum meruit*, or under a special agreement.

All the attempt that was made to place a check upon those persons who chose to practice, whether qualified or not, or who were vicious in their habits, was made in Second Revised Statutes, whereby it was declared to be a misdemeanor for any person, while in a state of intoxication, to administer any drug or poison by which the life of the patient was endangered; and, if death should ensue from improper treatment of a patient while in such state of intoxication, the person administering was liable for manslaughter in the third degree; that is, to imprisonment in the State prison for not less than two nor more than four years.

For a period of twenty years this seems to have been the only requirement of the law, and during this time various efforts were made to induce legislation on this important topic. No action was taken by the Commonwealth until May 11, 1874, when an act was passed regulating the practice of physic and surgery throughout the State. The passage of this act was secured through the joint efforts of the various medical societies throughout the State, and through petitions to the Legislature, signed by medical men, showing that the profession of physic and surgery was brought into disrepute by the number of men who were practicing without the required possession of a medical education.

The law is as follows:

ACT TO REGULATE THE PRACTICE OF MEDICINE AND SURGERY IN THE STATE OF NEW YORK.

Chapter 436.

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

SECTION 1. Every practitioner of medicine or surgery in this State, excepting licentiates or graduates of some medical society or chartered school, shall be required, and they are hereby commanded, to obtain a certificate from the censors of some one of the several medical societies of this State, either from the county, district, or State society: which certificate shall set forth that said censors have found the person to whom it was issued qualified to practice all of the branches of the medical art mentioned in it. And such certificate must be recorded in a book provided and kept for the purpose by the county clerk of each county in the State.

SEC. 2. The censors of each medical society aforesaid shall notify all practitioners of medicine and surgery of the terms and requirements of this act, and shall request such persons, so notified, to comply with those requirements within thirty days after such notification; and if such persons shall not, within the time specified in the notice, or within such further time as may be allowed by special arrangement with said censors, not exceeding ninety days, comply with the requirement herein made, of physicians or surgeons, as the case may be, such persons shall thereafter be subject to all the provisions and penalties prescribed by this act for any violation of the same, and the president of the society making such request shall, and he is hereby required to, at once commence the proceedings authorized by this act against such person.

SEC. 3. It is hereby declared a misdemeanor for any person to practice medicine or surgery in this State unless authorized so to do by a license or diploma from some chartered school, State board of medical examiners, or medical society, or who shall practice under cover of a medical diploma illegally obtained; and any person found guilty of such misdemeanor shall, for the first offense, be fined not less than fifty nor more than two hundred dollars. For any subsequent offense, not less than one hundred nor more than five hundred dollars, or by imprisonment not less than thirty days, or by both imprisonment and fine; and all such fines shall go into the county treasury of the county bringing such action.

PASSED May 11, 1874.

The law of 1874 continued without change until 1880, when the following act was passed by this State:

AN ACT TO REGULATE THE PRACTICE OF MEDICINE AND SURGERY IN THE STATE OF NEW YORK.

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

SECTION 1. A person shall not practice physic or surgery within the State unless he is twenty-one years of age, and either has been heretofore authorized so to do, pursuant to the laws in force at the time of his authorization, or is hereafter authorized so to do as prescribed by chapter seven hundred and forty-six of the laws of eighteen hundred and seventy-two, or by subsequent sections of this act.

SEC. 2. Every person now lawfully engaged in the practice of physic and surgery within the State shall, on or before the first day of October, eighteen hundred and eighty, and every person hereafter duly authorized to practice physic and surgery shall, before commencing to practice, register in the clerk's office of the county where he is practicing, or intends to commence the practice of physic and surgery, in a book to be kept by said clerk, his name, residence, and place of birth, together with his authority for so practicing physic and surgery as prescribed in this act. The person so registering shall subscribe and verify, by oath or affirmation, before a person duly qualified to administer oaths under the laws of the State, an affidavit containing such facts, and whether such authority is by diploma or license, and the date of the same and by whom granted, which, if willfully false, shall subject the affiant to conviction and punishment for perjury. The county clerk to receive a fee of twenty-five cents for such registration, to be paid by the person so registering.

SEC. 3. A person who violates either of the two preceding sections of this act, or who shall practice physic or surgery under cover of a diploma illegally obtained, shall be deemed to be guilty of a misdemeanor, and, on conviction, shall be punished by a fine of not less than fifty dollars nor more than two hundred dollars for the first offense, and for each subsequent offense

by a fine of not less than one hundred dollars nor more than five hundred dollars, or by imprisonment for not less than thirty nor more than ninety days, or both. The fine, when collected, shall be paid, the one half to the person or corporation making the complaint, the other half into the county treasury.

SEC. 4. A person coming to the State from without the State may be licensed to practice physic and surgery, or either, within the State in the following manner: If he has a diploma conferring upon him the degree of doctor of medicine, issued by an incorporated university, medical college, or medical school without the State, he shall exhibit the same to the faculty of some incorporated medical college or medical school of this State, with satisfactory evidence of his good moral character, and such other evidence, if any, of his qualifications as a physician or surgeon as said faculty may require. If his diploma and qualifications are approved by them, then they shall indorse said diploma, which shall make it, for the purpose of his license to practice medicine and surgery within this State, the same as if issued by them. The applicant shall pay to the dean of said faculty the sum of twenty dollars for such examination and indorsement. This indorsed diploma shall authorize him to practice physic and surgery within the State upon his complying with the provisions of section two of this act.

SEC. 5. The degree of doctor of medicine, lawfully conferred by any incorporated medical college or university in this State, shall be a license to practice physic and surgery within the State after the person to whom it is granted shall have complied with section two of this act.

SEC. 6. Nothing in this act shall apply to commissioned medical officers of the United States army or navy, or of the United States Marine-Hospital service. Nor shall it apply to any person who has practiced medicine and surgery for ten years last past, and who is now pursuing the study of medicine and surgery in any legally incorporated medical college within this State, and who shall graduate from and receive a diploma within two years from the passage of this act.

SEC. 7. All acts or parts of acts inconsistent with the provisions of this act are hereby repealed.

PASSED May 29, 1880.

The State Medical Society.

Medical societies were first established in this State in 1806, when an act was passed incorporating a society under the name of the Medical Society of the State of New York. In 1813 a general act was passed, entitled "An act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this State."

The powers and duties of the Medical Society of the State were also defined, and the society was made up of members selected from the State at large. The State was divided into four great districts, and the members from each district into four classes, one class to go out of office annually. At their annual meeting they were permitted to elect permanent members by ballot, provided no more than two such members should be elected in any one year. These permanent members were to be entitled to all the privileges of members.

This was amended in 1845 so that the number allowed to be elected permanent members was increased to two from each senatorial district. This society was originally composed only of delegates from the various county medical societies, but in April, 1818, the incorporated medical colleges of the State were each allowed one delegate to repre-

sent them in the society, and these delegates were declared to be entitled to all the privileges and subject to the same regulations as those from the county medical societies. Subsequently the hospitals were each allowed to send one, and the New York Academy of Medicine five delegates.

The Governor and Lieutenant-Governor of the State, the judges of the higher courts during their term of office, all members of the Legislature who were physicians, and all former delegates to the society, were to be *ex-officio* honorary members. They were to have the privilege of a seat at the meetings and of taking part in the discussions, but they could not vote or be eligible to any office. The society is now composed of delegates, permanent members, and honorary members.

Each county medical society is entitled to send as many delegates as there are members of Assembly from the county in which the society is situated.

The term of office of delegates is four years, and, as nearly as possible, one fourth of the whole number is annually elected.

The society is allowed to hold property, both real and personal, not to exceed the sum of five thousand dollars. It is empowered to make such by-laws and regulations relating to its affairs, concerns, and property—relative to the admission and expulsion of members—relative to donations or contributions—as a majority of the members at their annual meeting shall think fit and proper; provided that such by-laws, rules, and regulations be *not contrary to, nor inconsistent with, the Constitution and Laws of this State or the United States.*

The authority derived from Section 9 of the act of 1813, whereby it was empowered to examine students who should present themselves for that purpose, and give diplomas under the hand of the president and seal of the society, thereby authorizing them to practice medicine or surgery, or both, was repealed by the act of May 29, 1880. It has a general supervisory jurisdiction over the various county medical societies, and these are required to file copies of their by-laws with its secretary, to be submitted for examination.

Any member of a county society who shall feel aggrieved at the action of such society in enforcing discipline among its members, or any applicant who shall have been refused a certificate by the censors of such society, shall have the right of appeal to this society.

If any county medical society shall neglect to perform any of the acts required to be done by it by the laws of this State, or shall do acts which may be derogatory to the honor of the medical profession, or shall oppose or neglect to comply with the by-laws of this society, it shall be admonished; and, if it is deemed necessary for the public good that its corporate rights should be for a time suspended, it is the duty of this society to apply to the Legislature for such purpose.

(To be continued.)

THE BOTHRIOCEPHALUS LATUS.—M. Balbiani, professor of comparative embryology in the College of France, requests physicians to send him specimens of the rings or the ova of this parasite.

PUERPERAL FEVER:

AN OUTLINE OF ITS NATURE, MANIFESTATIONS, AND MANAGEMENT.*

BY EDWARD L. PARTRIDGE, M. D.,

PROFESSOR OF OBSTETRICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

PUERPERAL fever is a term of vague meaning, a relic of the views of earlier days, when it was believed that certain serious and fatal illnesses which sometimes follow parturition depended upon a special, zymotic poison. At the present time we are able to classify the various affections, which were formerly included under the general name, under more appropriate titles, with a clear understanding of their nature and manifestations, though some minor points in pathology are still unsettled. For convenience we may adopt that classification of Spiegelberg which is chosen by Lusk in his chapters which contain one of the most clear considerations of the subject available to the English-reading student. The febrile conditions of the lying-in period may be studied as follows:

1. Inflammation of the genital mucous membrane, endocervicitis and endometritis.

a, superficial; *b*, ulcerative.

2. Inflammation of the uterine parenchyma and of the subserous and pelvic cellular tissue.

a, exudation circumscribed; *b*, phlegmonous, diffused, with lymphangitis and pyæmia (lymphatic form of peritonitis).

3. Inflammation of the peritonæum covering the uterus and its appendages. Pelvic peritonitis and diffused peritonitis.

4. Phlebitis uterina and para-uterina, with formation of thrombi, embolism, and pyæmia.

5. Pure septicæmia—putrid absorption.

A practical study of the clinical history and pathology of these affections as they present themselves in the puerperal patient leads to the conviction that there is in the vast majority of cases an underlying septic element in their causation. In a small proportion of cases the febrile condition depends in the outset upon some one or more of these local conditions, there being no septic poisoning until a later period, when the peculiarities of the puerperal patient favor and bring it about. We meet, also, a few rare instances of these conditions in which we may believe that we have simply the manifestations of local affection from beginning to end. The truth of this would be questioned by some, however, who would regard such cases as presenting the septic element, but in very mild form. Yet I can not believe that the woman recently delivered may not suffer from cellulitis or peritonitis, as well as that these diseases may arise unconnected with child bearing or septic infection. In almost every instance, however, in which we have full facilities for clinical and pathological examination, even when organs remote from the parturient tract are the seat of lesions which have caused the fatal result, we are able to discover the in-

dications of the absorption of septic poison at some situation in the genital organs, and the progression of this poison to and into the general circulation—indications which, in the light of recent and accepted views upon septicæmia as a disease, are unmistakable.

The facilities for the introduction and development of septic poison in the lying-in woman are many, while the disease itself has inherent capability of development of peculiar intensity. Following parturition we have always the placental site, and, in many cases, lacerations of the cervix, vagina, and perinæum. If to these surfaces there is the contact of septic material, its absorption is extremely likely to occur. Prolonged contact or bathing of wounds with fluids containing this poison is much more likely to produce septicæmia—and that too of serious character—than contact for a short time, and the anatomical arrangement is such that we find retention of fluids in contact with these absorbing surfaces to be an easy thing. Until a wound is in a healthy, granulating, or a sealed condition, there is increased danger of septic absorption. In all puerperal wounds of the genital tract, their production by pressure, laceration, and bruising causes them to occupy a number of days before reaching a healthy condition of repair. The placental site, too, affords easy ingress to the poison, owing to the numerous large and often patulous uterine sinuses.

Septic material may be brought in contact with the placental site and with wounds of the vagina in two principal ways, and we may divide our cases, therefore, into *auto-genetic* and *hetero-genetic*.

Auto-genetic cases are those in which the septic poison originates with the individual who is sick. They are produced by decomposition of blood, fragments of secundines, inflammatory products, and sloughing tissues which are in close proximity to surfaces capable of septic absorption.

Hetero-genetic cases, or those in which the poison is supplied from other sources than the patient herself, arise from exposure to atmosphere containing emanations from patients suffering from septicæmia, erysipelas, scarlatina, and diphtheria, or from direct contact and inoculation with secretions from such patients—other media than the atmosphere being carriers of the poison. Decomposing animal tissues, pus, and blood also develop the virus of the disease.

The introduction of the poison may be by unclean instruments of all kinds, by unclean hands, or through the air of the sick room poisoned by any of the agents already mentioned.

Nature and Mode of Action of the Septic Poison.—Many and interesting are the studies upon these points, and it would be improper to omit some statement of the more advanced views of pathologists with reference to sepsis. There is so much, however, that is and must be speculative that it seems wise to exercise some conservatism and not too hastily to accept these views, however ingenious they may be. The power of self-increase of the poison, until from a small amount of the putrid fluid there is extensive production of the contagious principle throughout the organism, has led to the close scrutiny of the component parts of such fluid, and we have learned that there are universally present certain organisms, variably known as bacteria or micrococci.

* Read before the Obstetrical Section of the New York Academy of Medicine, December 27, 1883.

These are regarded as the *contagious principle* by many observers, and it is claimed that they enter the circulation through lesions of the capillaries, veins, and lymphatics, and undergo self-multiplication. The white blood-corpuscles are claimed to be the carriers and disseminators of the micrococci. It is further known that in cases of septicæmia these organisms are to be found at the presumed site of inoculation, along the lines of diffusion of the septic poison, in the blood itself, at the seat of the puerperal inflammations of distant organs, as well as in the organs which perform duties of elimination. Accepting this view, rather than that of an essential, zymotic poison, affords ready explanation of the *multiform* lesions of puerperal fever—this variation of lesion being chiefly due to the varying grades and extent of lymphatic or vascular permeation. Another reasonable thought is that there may be variation in the quality and kind of this microscopic poison producing variety of lesion. If, as Lusk has aptly suggested, our best instruments fail to enable us to distinguish the ovum which is to produce a mouse from one that will produce a tiger, though the ovum is at least one hundred times larger than the micrococcus, is it not possible that these septic organisms are not always identical, though they have monotonous appearance of form? This thought is in accord with views expressed by students of the subject. It can not be doubted that these microspores play some important part in the development of septicæmia, though certain conservative observers are yet unwilling to give them an essential, ætiological position, preferring to regard them as one of the results rather than the cause of the affection. Returning to the classification of Spiegelberg, we have to consider, first,

ENDOCOLPITIS AND ENDOMETRITIS.—The simpler forms of these conditions are commonly produced by prolonged or difficult labor, in which the genital tract sustains unusual pressure and irritation from contact with the child. The vagina has superficial erosions and ulcers, giving rise to *considerable purulent and sanguinolent discharge*, exuberant granulations being often found there and on the cervix. This discharge may be *variable in amount, and offensive* at times. The *labia are swollen*, and there are *pain, tenderness, and heat* in the genital region. The *uterine cavity* affords discharge containing some *pus and blood*; the *uterus* remains *large and flabby*, with some *œdema of the cervix*. *Mild traumatic fever* continues for a few days, until healthy repair is established.

Another form of endocolpitis and endometritis, known as *ulcerative, diphtheritic, or septic*, is much more serious. Here we find in the lining of the genital tract *deep and virulent extension of the ulceration* until in some cases the deeper muscular structures are extensively laid bare. The *ulcers* have a *grayish surface*, which—in hospital cases chiefly, sometimes elsewhere—has a membranous character not differing essentially from that of diphtheria, fibrinous fibrillæ, blood globules, and micrococci being present. The *discharge* is *very offensive, brownish and sero-purulent*, containing *fragments of necrosed tissue*. These cases may terminate in general septic invasion, or, more commonly, after a febrile condition of a week or more, the ulcers take on a more healthy character and recovery takes place. The process of healing

should be watched in order that *atresia vaginae* may not result from agglutination of opposed ulcers.

METRITIS.—When the endometrium is inflamed, the subjacent uterine structure participates to a greater or less extent in the process. Instances in which the muscular and connective tissues of the uterus are extensively involved are known under the name of metritis, which, as a disease, is never unassociated with some of the other puerperal lesions. *Originating* sometimes from *traumatic* and sometimes from *septic* causes, it occasionally happens that there are not only molecular, but also *necrotic changes*, until a considerable portion of the structure of the uterus is lost. The earlier condition is one of *œdematous infiltration* of muscular and connective tissue, and the *abundant lymphatic network* of the uterus takes up active morbid action. *Collections of pus and micrococci* often form in parts of the uterus. The inflammation usually extends to adjacent structures, and blood-poisoning often occurs. The *febrile disturbance* in metritis is of *higher grade* and more prolonged than in endocolpitis and endometritis. *Pain* is present, with *offensive, purulent lochia*.

PARAMETRITIS (*pelvic cellulitis*) is the *most common* of the puerperal inflammations, and may be of non-septic or of septic character. In the *former case*, the exudation, which may be *localized or general*, is of sero-lymph nature, and the febrile disturbance is simply symptomatic of the inflammatory action; temperature ranging from 101° to 103°; pulse 92 to 120. In the *septic form*, there is an *œdematous infiltration*, local or general, in the cellular tissue surrounding the uterus. Micrococci are present in it, and the morbid process can usually be traced from a point or points of inoculation in the uterus along the lymphatics, which, as well as the sinuses, generally contain pus. The febrile action is higher than in the non-septic variety (temperature 103° to 105°), and there is greater constitutional depression, as indicated by feeble and rapid pulse (130 to 140), profuse sweats, gastro-intestinal irritability, and nervous prostration.

The *local indications* of parametritis are *pain and tenderness*, appreciated by supra-pubic and vaginal examination, usually more marked toward one broad ligament than toward the other. There may be *diminished, or increased and offensive lochia*. Any attempt to examine regarding *mobility* of the uterus is *very painful*. *Urination* is *slow and painful*. If the exudation is general, the examining finger obtains a *sensation of fullness and boggyiness*. If, as often happens, the affection is unilateral, there will be an appreciable, *firm, tender swelling* of circumscribed area. This exudation reaches its greatest extent about the end of the second week. There may be sufficient deposit to be recognizable in the iliac region. Cases may terminate in *resolution*, the inflammatory mass becoming less tender and smaller, gradually undergoing absorption. *Suppuration* may occur, the case be much protracted, and abscesses of considerable size may spontaneously discharge in the iliac region, vagina, rectum, or bladder. In all cases we are liable at any time to have *septicæmia* and *pyæmia* as grave and sometimes fatal complications.

PERITRITIS (*pelvic peritonitis*) is inflammation of that part of the peritoneum which covers the pelvic viscera. It

is often associated with parametritis, owing to proximity of structure, and presents somewhat similar symptoms, though there are certain points of difference in the two diseases. There may be moderate exudation only, sufficient to impair the mobility of the uterus or produce agglutination of surrounding viscera. Occasionally the exudation is abundant, leading to a swelling in the iliac fossa which may become as large as a good-sized orange, resembling that of cellulitis, though situated at a higher level, and less liable to suppuration. When of septic character, the lines of diffusion from the site of inoculation are apparent on autopsy, the exudation is purulent with presence of small subperitoneal abscesses; phlebitis and lymphangitis are present, and the ovaries are commonly inflamed and softened.

Symptoms are fever, pain, tenderness, and tympanites in the hypogastric region, with absence of marked vaginal signs of cellulitis, it being remembered, however, that the conditions are often associated. There may be extension from pelvic to general peritonitis; or, the pelvic peritoneal inflammation being secondary to septicæmia, the constitutional disorder may be more marked than the local signs.

GENERAL PERITONITIS is common as a puerperal affection, there being two principal varieties. One form arises as a result of *septicæmia*, there having usually occurred metritis, cellulitis, or pelvic peritonitis, the lymphatics being chiefly engaged in diffusing the poison (peritonitis lymphatica). Another form is primary, or an extension of the pelvic variety, there having been no—apparent, at least—preceding septic absorption. In the *septic* form, the pain and tenderness which one expects to attend general inflammation of the peritoneum are wholly secondary to the prostration of vital powers due to the blood-poisoning. The abdominal cavity will contain fluid, sero-purulent exudation, greenish or brown, and offensive. The intestinal walls are distended, and after death will be found softened and readily torn. The disease comes on insidiously, sometimes no pain being present of sufficient intensity to require opiates. Similar exudation is often found in the pleura and pericardium, associated with septic peritonitis. Loose, diarrhæal movements are not uncommon. The most prominent sign on which to base a diagnosis will be marked, persistent abdominal distension, there being indications of septicæmia. There may be no marked septic lesions in the uterus and its appendages.

General peritonitis, when its septic origin is absent or doubtful, affords abundant lymph exudation with some pus. The abdominal organs become agglutinated. The febrile movement is attended by high temperature, severe pain and inflammatory excitement, followed usually by prostration. Vomiting, delirium, tympanites, and constipation are common, the latter often followed by diarrhæa. A severe chill is sometimes the initial symptom of the attack.

SEPTICÆMIA is a disease of protean character. It may be of such virulent type that blood dissolution is the only lesion, death occurring before the development of any septic inflammation. In such cases all the organs are softened, and the blood shows little or no disposition to post-mortem coagulation. The temperature rapidly rises to a high degree (upward of 106°), extreme nervous prostration occurs,

and death may result in from twenty-four to forty-eight hours. If the disease takes a less intense course, though of the same general character, the temperature may continue between 104° and 106° for several days; vomiting, delirium, and sometimes diarrhæa will be present, few patients recovering, the duration of the attack being less than a week.

In other forms of septicæmia the blood-poisoning is not so virulently felt, though the results may be as serious. The diffusion of the poison is more gradual, its effects are less striking, and the patient may succumb after many weeks of suffering, or finally recover. When purulent infection occurs, the symptoms are clearly demonstrable after the second week. *Chills and profuse sweats recur, the temperature rises and falls*, though never reaching normal, the stomach is irritable, the skin becomes yellow, tongue coated and disposed to be dry, low delirium and hallucinations are at times present, the mental faculties are dull, and the respiration is shallow and hastened. There will be present, also, the indications of some one or more of the local, septic inflammations which have already been described. Peritonitis is present in fewer than half the cases. Metastatic abscesses, as the result of the blood changes, or of infected emboli, are common in the lungs, kidneys, liver, and about the joints. Hæmatogenous icterus may occur, and is to be regarded as a grave symptom.

PREVENTION AND TREATMENT OF PUERPERAL FEVER.—We encounter more cases of puerperal fever in hospital than in private practice, and it is in the former that prophylaxis becomes a question of great moment. An atmosphere uncontaminated by germs such as are developed by surgical cases, and those of zymotic poisoning, as well as by previous cases of puerperal fever, is necessary to the safety of lying-in patients. Inasmuch as the poison can be conveyed from place to place, physician, nurse, laundress, and visitors to the sick room should exercise great care lest they be the bearers. Bedding, clothing of attendants, hair and whiskers, instruments, hands, and especially finger-nails, are the media by which the poison may be conveyed to the patient. In prolonged labors it is necessary—in all cases proper—to employ disinfectant vaginal injections during labor. After labor, and in advance of septic indications, their not too frequent but judicious use is called for. The proper management of the third stage of labor, looking to the complete expulsion of secundines and clots, and to permanent uterine contraction, is important in the prevention of both auto- and hetero-inoculation.

In puerperal disorders which, in their inception, are not complicated by septicæmia, treatment does not differ essentially from that suited to cases of the same nature unconnected with parturition, except that special care is necessary, on account of the tendencies of lying-in women, to use the *disinfectant douche*, and to promote escape of pus from mucous surfaces and from abscess cavities. In cases of septicæmia, by the same means we avoid accumulation of the poison germs and reinfection. When the point of inoculation is in the uterine cavity, or when we know that this cavity contains decomposing fluid, warm and carbolic intra-uterine injections should be repeated every few hours, and they will usually cause prompt fall of temperature. Care is necessary

that the injections be made slowly, and the liquid be freely allowed to escape so as to avoid dangerous uterine distension, extension of the fluid into the peritoneal cavity, shock, and retention of poisonous material.

Sloughing tissues should be removed as early as possible, and contiguous, exposed surfaces should be covered with *iodoform*, in powder form or suspended in glycerin, in a ten-per-cent. mixture, or touched with *carbolic acid*, or with *tincture of iodine*.

In local or general parametritis the *early use of leeches* may lessen the extent of inflammation. When exudation is present, *vaginal injections of hot water* (110° F.) hastens its absorption, and external application of heat, as by *poultices*, is proper when the situation of the pelvic inflammation makes it practicable. Pelvic abscesses should be treated by *aspiration* or *incision*. In peritonitis, light warm *poultices of bran or flaxseed* are advisable.

Medicinal treatment should consist of *opiates* to relieve pain, *quinine*, judiciously, for its antipyretic and supporting effect, and *stimulants* when indicated. *Food* should be concentrated, nutritious, and easy of digestion. The importance of maintaining *unimpaired digestion* can not be over-estimated.

General blood-letting at any stage of septicæmia is improper. *Arterial sedatives*, as *aconite* or *veratrum viride*, may be useful in certain cases characterized by *circulatory excitement*, yet their *depressing effect* is so easily reached, and such close observation during their use is necessary, that great caution should be displayed with them, lest they be administered too freely or in unsuitable cases.

Salicylic acid, as well as quinine, given in large doses, may reduce temperature, and the wet pack, with careful avoidance of its depressing effect, is similarly suitable.

Tympanites, when excessive, causes pain and a depressing, reflex influence on the nervous system.

Stimulating enemata containing *asafoetida* and *turpentine*, or even *abdominal puncture* of the intestines by *fine aspirator needles*, will afford some relief.

A PLEA AGAINST PROPHYLACTIC INJECTIONS AFTER NORMAL LABOR.

By SIMON BARUCH, M.D.,
NEW YORK.

At this juncture it would indicate a certain degree of temerity to raise a voice in opposition to the doctrines now promulgated in this country in favor of antiseptic injections for purposes of prophylaxis in labor and childbed.

But when a man has attended nearly nine hundred cases of labor, in which almost every complication has been encountered, with the result of only one death from a fever process, and without resorting, until very recently, to any prophylactic measures other than strict cleanliness, he may be pardoned for regarding the present campaign against micrococci of possible destructive tendencies within the vagina and uterus as indefensible and somewhat unreasonable. What surgeons owe to Englishmen, obstetricians owe

to the Germans for antiseptic management. The energetic antiseptic treatment of wounds, introduced by the corypheus of modern wound management, Lister, was rapidly adopted, in a more or less modified form, in his own country and followed in other countries. But the application of Lister's principles and practice to obstetrics was enthusiastically taken up by the German gynecologists, and then by their obstetricians. It was soon ascertained that when septic processes were threatened within the genital passages after labor, systematic cleansing, with carbolized lotions, of the surfaces furnishing the material for these processes offered the most astounding results. No wonder, then, that these magnificent therapeutic successes were heralded abroad and rapidly adopted by general practitioners. If septic processes, which formerly destroyed many lives (in public institutions chiefly), may thus be easily shorn of their danger, why not nip them in the bud ere they assume serious proportions? This reasoning, too, was successfully applied when all serious febrile processes after labor were at once treated by vaginal or uterine antiseptic irrigation. And now the question naturally arose, Why may not Listerism be closely imitated by *prophylactic irrigations* of the genital tract? In this direction the strides have been rapid in Germany, and now unfortunately the practice is being popularized in other countries. In our country Dr. W. G. Wylie read a valuable paper last spring before the County Medical Society, becoming thus the active apostle of complete Listerism (including spray) in our city. More recently Dr. T. G. Thomas has embodied his views in an able paper read before the Academy of Medicine, and indorsed by several eminent gentlemen with an alacrity which appears surprising.

While he justly condemns prophylactic intra-uterine irrigation, he dwells, with his usual ability and impressiveness, upon the necessity of the view that "every woman who is to bring forth is to be treated as though she were to go through a capital operation."

Brennecke, in Germany, published some months ago a "Mahnungsruf" to midwives, in which he advocates the strictest antiseptic management of labor and childbed with much earnestness, and, in his defense against Dr. Abegg, who justly attacked his view, he concludes by saying that he "deems it criminal to neglect antiseptics in the widest sense in all cases of labor." *Reaction against active antiseptic irrigation after labor has already set in abroad*. Intra-uterine irrigations for prophylaxis are being rapidly abandoned, and I am glad to find Dr. Thomas energetically proscribing them. Hofmaier reports that in Schroeder's* clinic 509 normal labor cases were treated experimentally. Of these, 249 were not irrigated, with a percentage of 8 febrile cases; 260 were irrigated, with a percentage of 16.1 cases of illness. He is supported by Breisky,† Fehling,‡ Max Runge, and others, who report unfavorable results. But I can not subscribe to the necessity of resorting to *vaginal antiseptic injections* even for purposes of prophylaxis.

My own experience has, perhaps, been singular, but may

* "Zeitschrift für Geb. u. Gynäkol.," Bd. v, p. 174.

† "Zeitschr. für Heilkunde," Bd. i, Prag, 1880.

‡ "Jahresbericht der k. Landeshebammschule zu Stuttgart im Jahre 1879," p. 42.

be worthy of record here. In common with my enthusiastic friends, and especially strengthened in my then wavering temper by Dr. Wylie's paper, I adopted prophylactic vaginal injections last spring, ordering a three-per-cent. carbolyzed lotion twice daily in all cases of childbed. The result was unfortunate. While I formerly had rarely encountered severe febrile processes after labor, I at once found myself favored in this direction. Six cases of severe fever, of undoubted septic origin, occurring from the fifth to the ninth day, rewarded my innovation. Two cases had been attended in labor by another gentleman, who had ordered vaginal antiseptic injections after labor. These came under my treatment on the fourth and sixth day, owing to my friend's illness. There were three primipare in the total number, and the localities were quite diverse—one case in West 161st Street, one in West 140th Street (neat cottage standing alone), one in West 158th Street, one in East 74th Street, one in West Fifty-fourth Street, and one in West Fifty-fifth Street. These cases were cared for by different nurses of average intelligence, claiming experience in vaginal injections. The fever was of severe type in four of these cases, but was controlled by a mercurial purge and large doses of quinine. I am confident that the trouble was due to disturbance of the sensitive and, in the primipare, surely wounded genital tract. Immediate perineal suture was resorted to in three of the cases, and the tear had healed and stitches had been removed before the advent of fever. That the frequent and probably clumsy introduction of the syringe-point may produce fever is emphasized in a recent paper by Kehrer,* read before the Fifty-sixth Congress of German Naturalists and Physicians at Freiburg. Although he is an enthusiastic advocate of prophylactic bichloride-of-mercury irrigations, he insists that the attendants must be well practiced, to prevent tearing recent wounds with the syringe-point, and possible inoculation with infecting germs. He saw cases in which fever did not fall despite the injections, but fell when they were omitted.

Dr. Thomas and Dr. Hunter also insist upon the vital importance of competent nurses, supervised by the physician.

That the average woman is unable to obtain skillful nursing can not be gainsaid. It is difficult to introduce painlessly the syringe-point within a tender vagina without exposing the parts; particles of infecting material may be carried to the frequently torn and spongy cervix; thrombi, which seal open veins, may be displaced, and thus admission gained for septic matter; the os being patulous, occasional entrance of the stream of water into the uterus can not be avoided. Recent adhesions of wounded surfaces may be disturbed. (See cases reported by Fischel, "Archiv für Gynäkolog." Bd. xx, Heft 1, p. 36, etc., in Breisky's "Klinik.") These and other objections, which will present themselves to the thoughtful practical physician, impel me to avoid all injections for prophylaxis and to rely upon that best of all antiseptics—simple cleanliness on the part of physician and nurse before, during, and after labor—in all cases. The fourth, fifth, and sixth, and even the seventh clauses of Dr. Thomas's "Prophylactic Measures" are admirable, and can not be too strongly insisted upon, although

it would seem that every modern obstetrician should require no injunctions on these points.

The experience of many practitioners will doubtless coincide with mine in this respect; I imagine that it would be difficult to persuade men who have seen a large obstetric practice—especially outside of large cities—to adopt the new method of vaginal prophylaxis, when they have enjoyed the immunity from serious febrile sequelæ which I have observed in the practice of others as well as in my own.

With a view to prevent the mischief which is likely to be done by the indiscriminate washing of the vagina after labor, among the younger members of the profession, I raise my voice of warning at this juncture. Guided by the justly eminent gentlemen who advocate antiseptic vaginal prophylaxis, every new-fledged obstetrician, in country and town, will rush to the rescue of "septicaely threatened parturient" women (all), and scorn every one else who does not pursue this practice as an old fogey. The various therapeutic fashions which have flourished since the beginning of medicine bear witness to the probability of this unhappy result. I plead for a pause of reflection, and would urge upon our leading obstetricians to stem the tide ere it be too late; and especially to bear in mind that the vast majority of their students will practice their art in towns and country districts, where pure air, seconded by cleanliness of physician, patient, and nurse, will accomplish more for prophylaxis than the combined forces of all the germ-destroying measures. The idea can not be successfully maintained that there is any similarity between an artificial traumatism and the utero-vaginal surface after labor in the matter of prognosis.

The natural course of an artificial wound is in the direction of kindly healing; this is exemplified in severe fractures (subcutaneous). It has been found, however, that an immense number of traumatisms fail to follow this natural process, and that a large proportion of these failures are due to certain septic processes, due to causes existing without and within the wounded part. Some of our best surgical authorities have arrived at the conviction that this great source of failure and death may be removed by antiseptic management, by Listerism, pure or modified. I yield to no one in acknowledging with a grateful heart that I have lived to labor in this happy surgical era. In gynecology the same conditions exist as in other surgical operations. But, when we come to the utero-vaginal tract after labor, quite another experience confronts us. Here, too, we have a traumatism, not artificially, but naturally induced in a physiological process. But, instead of a large percentage of deaths, as is the case after serious surgical operations (to which Dr. Thomas would liken the case of a woman in labor), we are met with a very small percentage of mortality or failure. The vast majority of puerperal women escape sepsis altogether. The latter is chiefly prevalent in maternity hospitals, and, in late years, since the gospel of cleanliness has been diffused among the profession, these institutions present, in many instances, as good a record as can be found in private practice. I may cite Max Runge's* report from Gusserow's clinic ("Bemerkungen über eine Puerpe-

* "Archiv für Gynäkologie," 1883.

* "Zeitschrift für Geburtsh. u. Gynäkolog.," Bd. v, p. 145.

ralfiebreepidemie in der geburtshilflichen Klinik der Charité"). He says that the prophylactic uterus-irrigations in childbed, which had been introduced experimentally at the beginning of a so-called epidemic of puerperal fever, favored the spread of the septic process. Runge resorts to injections only when evidences of decomposition present themselves. He reports 1,500 cases which were treated expectantly, with a mortality from sepsis of 0.39 per cent., and this result was obtained when puerperal fever was supposed to be epidemic. Fischel* reports the mortality in Breisky's clinic (where irrigations are used only when needed), out of a total of 933 labors, only 0.21 per cent. Fehling† reports that, in 1879, there occurred 415 cases of labor in his institute, of which not one died of puerperal fever, despite the fact that not a single irrigation was resorted to. Hegar ("Discussion of Sublimate Irrigation") orders injections before and after labor, but rarely in childbed, except when the lochia are offensive.

Can I offer a more eloquent plea than the enormous experience of these clinicians, for the "*noli me tangere*" plan, which I now desire to emphasize?

The immense clinical material of the German obstetricians and the precision of their observations by skilled clinical assistants invest their statements with peculiar interest and value. They can not be equaled by the experience of American authorities in this respect. So far as I have been able to ascertain, the only utterance from a regular maternity institution favors the view I have espoused. In the discussion of Dr. Wylie's valuable paper, Dr. Garrigues (surgeon to the Maternity Hospital, Blackwell's Island) says that in hospital practice he had not obtained the results he expected from it (irrigation, etc.) as a prophylactic measure.

As I seem to stand single-handed and alone in opposition to the universal application of prophylactic antiseptic injections in and after labor, I am reassured by being able to fortify myself with the authority of so eminent a man as Breisky. Breisky‡ advocates the abolition of all injections, vaginal as well as uterine, unless there be evidences of decomposition. He maintains that in normal labor Spiegelberg's "*in Ruhe lassen*" of the puerperal genitalia should be the rule. He says that he has not been able to convince himself that the way to a greater and more secure limitation of puerperal mortality is to be found in a specially active prophylaxis, operating by regular injections into the inner genitalia. Although I earnestly oppose antiseptic injections for purposes of prophylaxis, I would enter zealously into the "curative measures" proposed by Dr. Thomas, especially on the first symptoms of a rising temperature attributable to septic or unknown causes.

But even in these cases I would suggest that an over-anxious interference by energetic and frequent uterine irrigation may not be necessary, and should be reserved for the more serious cases. Fortunately, we have in recent literature some valuable contributions to this subject. The discussion of Kehr's* paper on "Sublimate Injections" (in

the Fifty-sixth Congress of German Physicians and Naturalists) demonstrates the superiority of the latter to carbolic lotions, because it is cheaper, odorless, and more soluble. A few cases of mercurialization have occurred in women who had previously passed through a course of mercurial medication, and several cases of urticaria among physicians and attendants are mentioned from handling strong solutions.

An important observation was contributed by Kuestner, who obtained the uterine secretions direct from the organ by means of tubes, and discovered that the micrococci which abounded in them did not disappear promptly after carbolic injections, but always promptly after sublimate injections. It would appear from Bardeleben's experiments that a solution of 1 to 10,000 is sufficiently energetic. Hegar and Kaltenbach favored sublimate injections. Hegar "can not imagine a better antiseptic." But the most important contribution to this subject has been made by Ehrendorfer,* of Spaeth's clinic. He recommends iodoform pencils consisting of 150 grs. of pulverized iodoform, and 15 grs. each of gum arabic and glycerin and pure starch, which are easily soluble and flexible. As it has been demonstrated by Koenig that cases of iodoform intoxication are rare when not more than 10 grammes (150 grains, about) of pure iodoform are applied, there need be no apprehension of poisoning. He uses more frequently only 6 grammes (90 grains). They are applied as follows: After the fetus and secundines have been removed, the uterus is irrigated with a two-per-cent. carbolic lotion, one to two litres being consumed. So soon as the uterus is well contracted, the iodoform pencil is grasped by a disinfected polypus forceps near its middle; it is dipped in carbolic water. Now, one half of the other hand is introduced into the vagina of the woman, whose hips have been previously elevated, so that the index and middle finger lie behind the cervix. The other hand, holding the forceps with grasped iodoform pencil, introduces the latter into the cervix; and, while one finger of the left hand supports its lower end, the forceps is loosened and the pencil is pushed into the uterus as far as possible. The cases in which iodoform was used as an intra-uterine pencil were all abnormal labors, or labors followed by purulent endometritis, etc. He reports in detail twenty-nine cases, case two (2) of which was brought to a successful issue after carbolic intra-uterine injections had failed and had become very irksome because of the patient's somnolence and the extremely sensitive and erysipelatous condition of the external genitalia. Another striking case is one (22) in which, despite continued fever, several deep vaginal ruptures healed under local application of iodoform. Another case (27) presented a gangrenous condition of the vagina; and, again, another case, not reported in the list, presented a remarkable result of healing by iodoform after gangrene had set in.

The cases were nearly all severe, coming frequently during an uncompleted labor, or after a badly conducted one, to the clinic. Despite the unfavorable prospect of these cases, the iodoform pencils were used rarely—only once or twice in many cases during their whole progress.

* "Ueber die Verwendung der Iodoformstäbchen," u. s. w., "Arch. f. Gynäk.," Bd. xxii, Heft 1.

Here, then, we have the perfection of antiseptic management after labor, presenting a maximum of advantage (antiseptis) with a minimum of disadvantage (disturbance).

If, therefore, I should observe after any normal labor a rise of temperature, not attributable to causes unconnected with the local puerperal condition, or even not traceable to any known cause, I would give the patient the benefit of the doubt and begin antiseptic treatment. The same should be resorted to if the lochia present evidences of decomposition, or if a chill or general malaise can not be accounted for. The vagina should first be thoroughly irrigated with a feeble stream of solution of bichloride of mercury, 1 to 2,000. An iodoform suppository should be placed within the vagina. If symptoms do not yield, the vagina should again be irrigated; the syringe being cleaned, the uterine cavity should next be injected. This precaution is necessary to prevent the introduction into the uterus of septic matter from the vagina on the point of the syringe tube. When the uterus has contracted, an iodoform pencil, made according to Ehrendorfer's direction, and containing 90 to 100 grains of pulverized iodoform, should be pushed well into the uterine cavity.

The disinfecting injections and the pencil should be renewed whenever the lochia again become offensive, or, if the temperature continues to rise, each time preceding the pencil by irrigation with a solution of bichloride of mercury, 1 to 2,000, or even weaker. It is important that the solution should not be hot, because a high temperature will constrict the parts for a time, and prevent the local action of the iodoform; a temperature of about 90° is proper. A small bunch of tow or absorbent cotton may now be placed under the genitals to receive the iodoformized lochia. According to Ehrendorfer's experience, an interval of two to four days will elapse ere renewal of the pencil will be required. In conclusion, I would again most earnestly urge a careful consideration of this question of prophylactic injections, and I trust that in the forthcoming discussion at the Academy of Medicine the practice will receive the condemnation it deserves from more able advocates than myself.

Sanctioned as it is by some of our highest and most justly eminent authorities, the use of prophylactic injections in the puerperal period will surely become a general practice, if the subject be not calmly discussed in the light of experience. If I have aroused attention to the danger which threatens the puerperal woman of the future from this practice, I shall be content. Nothing but a strong sense of duty has prompted me to venture to differ from men whose views I have always regarded with respect, from whom I have learned much in the past, and by whom I expect to be guided largely in the future, whenever their teachings do not conflict with the results of experience and common prudence.

"OPHTHALMISTS."—The "Medical Times and Gazette" begins an editorial article as follows: "The ophthalmologists, or, as our American cousins would say, the 'ophthalmists,' etc. This is a good specimen of 'Americanisms' of foreign coinage.

Clinical Reports.

NEW YORK HOSPITAL.

CLINICAL REMARKS BY ROBERT F. WEIR, M. D.

Saturday, November 24, 1883.

Catheter Fever.

GENTLEMEN: Some time ago I promised, instead of my usual operations, to devote an hour to the consideration of one or two practical points which could be illustrated by cases in the wards of this hospital, and I avail myself of the opportunity to fulfill that promise to-day. One of the points prominent in my mind relates to urethral or bladder difficulties. You may have seen in some of the medical journals a statement made by Sir Andrew Clark, president of the Clinical Society of London, to the effect that he had had brought to his notice, within the preceding year, five or six cases of what he was pleased to call "catheter fever." He meant by that, that certain elderly men, suffering from some urethral difficulty, had been to a surgeon, who passed a catheter, and that, when they came under his notice, they were affected with chill or fever, or both, the urine was more or less turbid, the mental faculties were impaired, and there were subsultus tendinum and other typhoid symptoms, terminating in death. Sir Andrew put the question to the society, What was the nature of the affection? The question was not then answered, although it was afterward pretty fully responded to by surgeons distinguished in genito-urinary diseases, notably Sir Henry Thompson and Mr. Reginald Harrison.

This is not an unknown disease at all; surgeons are constantly witnessing such ill effects of the introduction of the catheter, particularly in quite elderly people—people who have had trouble with the prostate and variable, incomplete retention of urine for a number of years. You know that, at about the age of fifty-five, enlargement of the prostate occurs, from unknown causes, in about one out of every three men, and, in about one person out of every twelve so affected, more or less retention of urine takes place, so that the patient is unable to empty the bladder completely. The urine which remains undergoes certain changes, and after a time may give rise to inflammation of the bladder. The patient may have to pass his urine a little oftener, particularly at night, and, as time goes by, other changes may take place, involving probably the ureters and kidneys also. For the relief of a certain annoyance of the bladder, or perhaps a complete retention, the patient finally goes to a physician, who introduces a catheter, and finds a considerable amount of residual urine.

What may finally result, after such relief has been afforded with an instrument, is what you see in the fresh specimen which I now show you. This kidney was taken from the body of a man who had a stricture, not very tight, but deep in the canal, which rendered the use of sounds necessary a number of times for its dilatation. On Sunday last, the surgeon who had charge of the patient passed a No. 23 (French) sound, and the next day the patient was seized with a violent chill. As the man had had malarial fever before, the elevation of temperature that took place (to 104° or 105° F.) was supposed to be due to that cause. Then the joints became affected, a cardiac murmur appeared, and, as the bladder symptoms were slight and did not appear sufficient to account for the patient's condition, it was supposed that he was suffering from an ordinary attack of rheumatism. No greater violence had been done in passing the instrument than on former occasions, but the patient, who in the mean time had been brought to the hospital, died yesterday morning, five days after the insertion of the sound. The post-mortem exami-

nation showed that the difficulty was not malarial or ordinary articular rheumatism, but that the symptoms were due to pyæmia, starting, perhaps, from a slight damage done the urethra by the passage of the sound. Either a nervous influence was produced at the time of the dilatation, or the changed condition of the urine poisoned the wound and the system, or, again, an extension of the inflammation may have passed to the bladder, up the ureters to the already diseased kidneys, and thus, to use a homely expression, fat was put into the fire. An acute inflammation was added to a chronic one, and destroyed the patient's life. In the specimen which I show you the disease of the kidney had not yet resulted in apparent abscess, but oftentimes you will find pus cells surrounding the tubules, constituting what is called interstitial suppurative nephritis, or the "surgical kidney." In some cases you will find the kidney presenting bloody areas, points of infarction, of a lighter color in their centers, which would evidently have terminated in abscesses. That condition is present here in a very marked form, and with the microscope many colonies of micrococci are seen; in other words, this is a septic process of the highest degree. Although the specimen is one removed from a young person, who had a strictured urethra, yet such conditions are also met with in the prostatic patient. There are other grades where the inflammation is not so intense, which we sometimes designate as a pyelitis, a condition not always recognized during life, but suspected on failure of the patient's powers, with the secretion of perhaps undue amounts of turbid urine, without other changes.

Under the heads of cystitis, pyelitis, and "surgical kidney," with or without appreciable abscess, may be grouped, clinically, the severer symptoms produceable by the introduction of an instrument into the bladder of an old or elderly man. Now, this "catheter fever" is something which every one of you will run against sooner or later, and what I want to impress upon you is the fact that it is more apt to occur the longer the prostatic trouble has existed. This is a strong reason, in my mind, for teaching elderly men so affected to use the catheter early. Sir Henry Thompson very properly urges the use of the catheter more than he did ten years ago, and yet, in my estimation, he still falls short of the mark, since he waits until the residual urine amounts to eight ounces before resorting to the instrument. I feel that, when as an old man has difficulty in passing his water, with incomplete emptying of the bladder, he should be taught to use the catheter so soon as this is recognized. On the first occasion he may find that its passage causes more or less irritation, perhaps a slight aggravation of his symptoms for three or four days, and he will think that your remedy is worse than the disease. He will argue that this trouble only compels him to get up once a night to urinate, and his water is perfectly clear; why, then, subject him to this annoyance? And you will find a good deal of difficulty in leading your patients to follow your advice; but I can assure you that, if you do so, you will anticipate pathological changes, and save them a good deal of subsequent trouble.

How are you going to avoid this "catheter fever" when you meet with a case of this sort which has continued for five, six, or eight years, or those cases in which it is most common—I mean where the patient is attacked with retention, and is completely unable to pass his water. Brodie and Thompson have taught us that in such a case, when we first introduce the catheter, after the patient has urinated, and find that the bladder contains a large amount of residual urine, we should not withdraw all of it, but leave half or two thirds behind. Now, this is very good advice, but how are you to tell how much is half or two thirds of the residual urine until it is all drawn off? You should do one of two things: either withdraw all the urine, and then do as I shall tell you in a moment, or else stop the flow of urine

when half a pint has escaped, and at each subsequent catheterization draw off a little more. I prefer, however, that you should act in this way: let the man pass what water he can in your presence, then introduce the catheter and empty the bladder, but do not leave the organ in its collapsed, wrinkled-up condition, as some have described it, attributing to this the cystitis that so often occurs; instead of so doing, throw into the bladder a quantity, equal to one third or one half of the urine withdrawn, of a solution of carbolic acid, 1 to 100, or a solution of boric acid, one drachm to the pint, or ordinary hot water, or, what I like above all, a solution of bichloride of mercury, 1 to 5,000. The quantity of the injection is to be diminished gradually until you get the bladder used to its contraction. The patient is also to be kept in the house for a few days, until tolerance of the instrument is fairly established.

In ordinary cases I prefer a rubber catheter, and I first test it, to make sure that it is very flexible and strong. The very supple silk catheter recently devised, like the one I show you,* rivals the rubber one, especially in durability, and answers its purpose admirably, but it is more liable to become contaminated than the rubber one. Before using the catheter, pass a carbolic-acid or corrosive-sublimate solution through it, to guard against the introduction of poisonous matter from without; and, so far as you can manage it, in order to prevent the entrance of air into the deeper urethra, introduce the catheter full of the antiseptic solution, and, on withdrawing it, pinch its end, and let it thus come out full of fluid. Use also iodoformized oil, five grains to the ounce, to grease it with, rather than the carbolized oil, which is inert.

I would speak more at length on this subject, but time will not permit. I hope, at any rate, that you will be led by these remarks to begin catheterization early in cases of enlargement of the prostate causing retention, thus preventing the development of those conditions which, in the older and neglected cases, are liable to result in "catheter fever" when they finally do come under treatment. Finally, remember that, although not absolutely proved, it is so nearly so as to be accepted, it is the septic influence of the catheter that initiates these changes; hence be particular to guard your patient in this direction as far as possible.

(To be concluded.)

NEW YORK, SATURDAY, JAN. 5, 1884.

PROSECUTIONS OF MEDICAL MEN.

IN so far as suits for malpractice are concerned, and, if we except abortion cases, in so far as criminal charges are founded in matters of medical practice, the annals of the prosecution of medical practitioners may be said to constitute almost an unbroken tale of malicious persecution. It is very much to the credit of Dr. Sayre that for many years past he has exerted himself to ameliorate this state of things by securing the passage of a statute obliging persons to bring suits for malpractice to secure the defendants against pecuniary loss in case of the failure of the suit. Such a provision would, of course, fail to secure against vexation and indirect loss, but it would undoubtedly go far toward checking frivolous prosecutions, and it is therefore very much to be regretted that thus far Dr. Sayre's efforts have proved of no avail. As matters stand now, malice is almost the only thing needed to bring any practitioner at any time into a position where he must feel doubt and anxiety as to how the jury will view the testimony, and a painful certainty of earning a newspaper fame that will prove anything but pleasant.

The law is properly very indulgent in the matter of allowing civil suits to be brought, even when the case seems very slender; but it must be said, to the credit of our prosecuting officers, that they are generally slow to countenance criminal proceedings in the absence of something tangible in the way of evidence to begin with. An instance has lately occurred in Loudon, however, which goes to show that the public prosecutor concerned has ideas somewhat at variance with this cautious way of doing things. Two general practitioners, having performed tracheotomy upon a child suffering from diphtheria, to save it from impending suffocation, had the misfortune to lose their patient, whereupon the father of the child brought a civil suit against them, claiming damages on the ground that a sore throat from which he had suffered was the result of his having sucked the tracheotomy tube, by their direction, to free it from secretions. In that suit the jury disagreed, and a new suit is now in course of trial. Pending this second suit, the mother went before a police justice and swore to an allegation setting forth that the two practitioners' treatment of her child had been improper, and charging them with manslaughter. Simply on the strength of this allegation, and without the slightest medical testimony, the public prosecutor undertook a criminal action in the case. When the case came before a magistrate, however, one medical witness was summoned, but his testimony proved to be of such a nature that, immediately after his cross-examination, the case was dismissed, the magistrate remarking that it was a case of "persecution, not prosecution."

Meantime the two surgeons are still involved in the second suit for damages, and it is, perhaps, to the fact of the additional indignity of the criminal process having been brought against them that they owe an influential movement of sympathy and assistance which has sprung up in their behalf. Although the persecuted surgeons do not seem to be in any way prominent members of the profession, the entire medical body of London is entering heartily into measures that are being taken for their relief, and it is exceedingly gratifying to find that such distinguished physicians and surgeons as Sir William Jenner and Sir James Paget are taking the lead in measures to provide adequate means of defense, and, better than all, in calling the attention of the Government to the need of an arrangement by which the public prosecutor may obtain the assistance of skilled advisers when he is solicited to institute prosecutions of medical practitioners.

THE ÆSTHETICS OF THE STOMACH-PUMP.

THE serenity of the professional sword-swallower, albeit rather the calmness of resignation than of any other state of mind higher in the scale of happiness, is quite as likely to win our admiration as the feat the fellow performs. But sword-swallowing, we must assume, is not usually indulged in as a pastime or as a piece of dissipation, but for money. Looking at the matter in the light of this consideration, we can understand that a gleam of satisfaction should light up the performer's face as he fondly wipes his blunt and polished weapon. Like the Alpine guides, he is cheered by the thought that "it is to eat macaroni." But, surely, there can be no such consoling reflection for him who is condemned to the routine employment of the stomach-douche. We are forced to infer, therefore, that there is some intrinsic quality in the rubber œsophageal tube—some delicate power of titillation—that confers upon its devotee a degree of ecstasy in comparison with which the mere commonplace *bien être* of the sword-swallower sinks into sullenness. At least this must be the case if we may judge from a woodcut that adorns an article on the subject in a recent number of one of our French contemporaries. The cut in question bears evidence, however, of having been furnished by the famous cutler, M. Galante, and may have been got up under his direction with the express purpose of bringing the instrument into fashion. Be this as it may, the face of man seldom wears a look of more exquisite jollity than in the figure referred to.

MINOR PARAGRAPHS.

PURPERAL FEVER AND ABORTION.

ACCORDING to M. Hervieux ("Gaz. hebdomadaire de médecine et de chirurgie," Nov. 9, 1883), out of 16,173 confinements that took place in the Paris Maternité, from the year 1861 to the close of the year 1872, 5,236, or 32.05 per cent., were premature. This may be accounted for, to a certain extent, by the unfavorable physical and moral influences generally affecting the beneficiaries of such institutions, and arising from their condition in life, they being for the most part unmarried women. But some other explanation is required for the fact that from 1861 to 1867 the percentage of abortions at the Maternité varied between 33.98 and 41.50, while from 1868 to 1872 it rose no higher than 27.57

—the lowest point being 18.99—with an evident tendency to decrease toward the end of this period. That is, during the latter term the proportionate number of abortions was less than during the former by over one third. The general causes already adverted to remained in operation throughout; and even when they were greatly aggravated, as in the years 1870 and 1871, the number of abortions continued to diminish. This state of things could not be attributed to meteorological conditions. Writers on veterinary subjects, however, make frequent references to the fact that cows sheltered in certain stables are especially liable to repeated abortions. Now, this, according to M. Franck and M. Ruloff, is the direct result of contagion. The former has ascertained that if matter from the genital passages of an animal, in which abortion has recently occurred, is introduced into the vagina of another that is pregnant, the latter will be caused to abort likewise—an effect due to the presence of micrococci or bacteria in immense numbers on the foetal envelopes, which ultimately bring about their decomposition. It is easy to see how readily this accident may take place in cow-stables, and how it may lead to an indefinite series of abortions. Hence we may infer the possibility of premature births occurring epidemically among human beings as the result of infection or contagion. The figures cited by M. Hervieux show, in fact, very clearly, that the years during which puerperal fever raged most fiercely at the Maternité were precisely those marked by the greatest number of abortions, and that the latter diminished in proportion as the sanitary condition of the establishment improved. Nevertheless, the premature births went on increasing for a considerable period after 1864, the year of highest mortality. This was because the puerperal contagion, like that of some other diseases, operates in different directions—striking, now the mother alone, now the unborn child, and now both together—while, in the reports of lying-in asylums, no regard is paid to the mortality of the newly born, the mothers' death-rate alone being taken into account. In short, it is proved by statistics that residence in these institutions tends to abridge the period of gestation, so that the longer a pregnant woman remains in one of them the less chance she has of reaching her full term. The practical conclusion is, that a woman in this situation should never be allowed to enter a lying-in hospital while puerperal fever exists as an epidemic within its walls; and at other times the date of her admission should approximate as closely as possible that of her expected confinement.

HOSPITAL SATURDAY AND SUNDAY.

It will not be known for some time yet how much has been contributed to the funds of the Hospital Saturday and Sunday Association this year, but the prospect is that the amount will be found to be considerably larger than last year. Of the 367 Protestant churches, 294 promised to take part in the work, whereas only 111 contributed last year. Although those regulations have been abolished that forbade donations to be appropriated in accordance with the wishes of the donors, it is to be hoped that contributors have very generally allowed their gifts to go into the general fund, for the association is much better able to judge of the requirements of individual institutions than most of those who give their money.

THE MEDICAL PROFESSION IN FRANCE.

It is cheering to learn that America is not the only country in which doctors are on the increase. According to a writer in a recent issue of the "Gazette hebdomadaire de médecine et de chirurgie," the number of practitioners (including physicians and *officiers de santé*, but not including midwives) has increased

from 14,376 to 14,848 since the last census was taken, in 1876; while the increase of the total population has not been sufficient to prevent the proportion of practitioners from rising from one in every 3,807 to one in every 3,235. It is the doctors that are growing in numbers, the *officiers de santé* having actually diminished. The latter constitute a lower grade of practitioners, the final disappearance of which is likely to take place without the need of any legal enactment for the purpose. The midwives are even more numerous, and the writer in question estimates that there could be only eighty confinements annually for each one of them, supposing that the doctors did no midwifery. How do these dames pass their time, he asks, when they are not making traction on the cord?

COPYRIGHT IN LECTURES.

THE question has often come up before the courts as to the extent to which oral lectures are the property of the lecturer, and subject to his control in the matter of publication. In this country several instances have happened in which the absolute right of the lecturer has been affirmed, but in many of these cases there have been collateral considerations which have tended to obscure the principle involved. A case has lately come before a Glasgow court in which these side-issues do not seem likely to be brought forward, and the decision may therefore be looked for with great interest, especially as the copyright law of Great Britain excludes university lectures from its action, and the case in question relates to such lectures. If the decision should be adverse to the lecturer, it may not prove to be applicable as a precedent in this country, since the exemption of university lectures from the operation of the British law may be held to be founded on the fact that the universities in that country receive their support from the State, which is not the case with us.

THE SURGEON-GENERALSHIP OF THE NAVY.

THE contest as to whether or not Surgeon-General Wales shall be his own successor, which has long been going on in a subdued fashion, has now reached a point at which it is likely to engage the attention of the country. Dr. Wales's chief rival is Dr. Horwitz, whose claim is grounded on seniority, and is said to be backed, in addition, by the personal preference of the Secretary of the Navy. The appointment is in the hands of the secretary, but it must be confirmed by the Senate. In view of the latter consideration, the report that nearly all the senators have either signed or are about to sign documents favoring the re-appointment of Dr. Wales becomes significant. The moral of the whole matter seems to be, that the Surgeon-General of the Navy ought to hold his office until he reaches the age for retirement, like the corresponding officer of the army. The medical corps would then be spared the chance of a recurrence of the disturbance attendant on such a contest every four years.

THE "ARCHIVES OF PEDIATRICS."

THE first number of a new monthly journal with this title has reached us, and we find both its contents and its appearance very creditable. As its name implies, it is devoted entirely to the diseases of infants and children. When we consider how much of the daily work of the general practitioner is made up of practice among children, the value of such a publication becomes apparent. The "Archives" is edited by Dr. William Perry Watson, of Jersey City. The first number, dated January 15, 1884, contains sixty-four pages of reading matter, including two original communications, a clinical lecture, a clinical memorandum, and a good variety of translations and abstracts.

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 1, 1884:

DISEASES.	Week ending Dec. 25.		Week ending Jan. 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	1	0	0
Typhoid Fever.....	26	5	8	6
Scarlet Fever.....	65	6	57	9
Cerebro-spinal meningitis.....	1	2	4	3
Measles.....	42	8	30	10
Diphtheria.....	40	24	36	20

SMALL-POX.—An outbreak of small-pox is reported to have taken place in the county jail at Newcastle, Del., last week.

A NEUROLOGICAL SOCIETY IN PHILADELPHIA.—The "Philadelphia Times" gives an account of a recent meeting of a number of the prominent neurologists of that city, at which resolutions were adopted looking to the organization of a neurological society. Dr. Kerlin presided, and Dr. Mills, Dr. Sinkler, Dr. Chase, Dr. Eskridge, and Dr. Brubaker were appointed a committee on organization.

THE MEDICO-LEGAL SOCIETY is to have a banquet at the Hotel Brunswick on Wednesday evening of next week, the occasion being that of the installation of the newly elected officers.

THE RECENT FIRE AT THE LUNATIC ASYLUM ON WARD'S ISLAND has moved the Fire Commissioners to consider what means can be taken to enable them to give more thorough protection to the island institutions. The most pressing need is thought to be the possession of means of conveying engines to the island more speedily than it can be done at present.

THE ENFORCEMENT OF SANITARY REGULATIONS.—It is reported that the Board of Health of Lancaster, Pa., has prosecuted a number of clergymen and physicians of that city for failing to make the quarterly returns required by its regulations.

THE ECLECTIC MEDICAL COLLEGE, of this city, is the defendant in a suit brought by the Attorney-General at the instance of the counsel of the Medical Society of the County of New York, the result of which seems quite likely to be the abrogation of the charter under which the institution does business. The main charge is, substantially, that the college has traded in its diplomas, even selling them in blank.

THE BOARD OF HEALTH has been obliged to curtail its force of sanitary inspectors, partly as the result of a reduced appropriation for salaries for the year 1884, and partly, it is understood, on account of certain changes in the organization of the working corps. These changes, which are attributed to the non-medical members of the board, acting in conjunction with the Health Officer of the port, an ex-officio member, are said to have been made against the wishes of Commissioner Johnson. Both on this account, and because the inspectors dismissed are among the most experienced that belonged to the corps, it is to be feared that the board will find itself crippled in its efficiency.

THE LAW REGULATING THE SALE OF POISONS seems to have been variously interpreted in Waterbury, Conn. An apothecary having been sued for damages for selling Fowler's solution without a prescription, and without labeling the bottle "poison," the defense was set up that Fowler's solution was not a poison within the meaning of the law. The Court held to the contrary, however, and the apothecary was convicted, but has appealed.

THE NEW AMBULANCE-CALL SYSTEM does not seem to have been brought to a high state of efficiency, to judge from the length of time it took lately to get an ambulance to the elevated railway station at Ninth Street and Third Avenue. By a round-about way, a signal was sent to St. Vincent's Hospital, but the ambulance was brought to police headquarters, instead of to the station in question. After having been sent to one place and another, the ambulance finally reached the place where it was needed, but the patient was then dead. The defect in the system seems to be that the signals are not sent directly to the hospital from the station where the emergency is reported, but by a circuitous course.

THE CITY CIVIL-SERVICE EXAMINATIONS have a medical aspect, it appears. The Mayor has appointed a commission to examine applicants for positions as nurses, attendants, orderlies, and the like, in the public hospitals. Dr. Thomas H. Burchard is said to be the medical appointee.

THE MASSACHUSETTS GENERAL HOSPITAL.—We learn that Dr. W. L. Richardson has been appointed a physician to the hospital, in the position made vacant by the death of Dr. Calvin Ellis.

M. PASTEUR'S CHOLERA COMMISSION is to be honored by the nomination of two of its members, M. Straus and M. Roux, as chevaliers of the Legion of Honor.

THE "COLLEGE AND CLINICAL RECORD."—With the December number, Dr. Frank Woodbury closes his connection with the "Record"—a connection which has been maintained for four years.

THE HEAVIEST HUMAN BRAIN observed thus far is said to have been that of the Russian poet, Turgenjeff, who lately died in Paris. It is reported to have weighed 2,012 grammes.

THE LOUISIANA STATE BOARD OF HEALTH.—One of the members of the board, Dr. Formento, has been nominated a corresponding member of the *Société d'Hygiène Publique*, of Bordeaux.

A DINNER IN HONOR OF M. CHARCOT was lately given at Lemardeley's, in Paris, the chief promoter being one of Professor Charcot's former pupils, M. Joffroy. More than eighty gentlemen were present, and the affair is said to have been unusually brilliant.

THE NEW SURGEON-GENERAL OF MASSACHUSETTS.—Dr. A. F. Holt, of Cambridge, who saw service during the late civil war, both as a medical officer and in other capacities, and for the past four years has been the Health Officer of Cambridge, has been appointed Surgeon-General of the State, on Governor Robinson's staff.

VIVISECTION IN GERMANY.—It is said that the German Government has been making inquiries of the various college faculties as to the facts in regard to the practice of vivisection in Germany, and that the Reichstag will soon be called upon to decide whether or not any legislation on the subject is necessary.

THE COOMBE LYING-IN HOSPITAL, DUBLIN.—Dr. Kidd's term having expired, Dr. Samuel R. Mason has been elected master.

BELLEVUE HOSPITAL.—Dr. E. Darwin Hudson, Jr., has been appointed one of the visiting physicians to the hospital, in place of Dr. Henry F. Walker, resigned.

THE NECESSITY OF AUTOPSIES in cases of death from unknown causes recently received a striking illustration in Massachusetts. A man having been found dead, it was suspected that his death was owing to injuries received in an encounter; but a medical examiner, after making a superficial examination of

the body, and discovering no external signs of violence, decided that it was unnecessary to carry the investigation further. He therefore reported the death as having been caused by heart disease, of which there seem to have been some signs. The town authorities being dissatisfied, however, a medical examiner from another town was called upon to make an investigation, and, on resorting to an autopsy, he discovered a dislocation of the cervical vertebra, thus, it is thought, revealing the fact that a crime had been committed.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending December 29, 1883:*

A. L. GIBON, Medical Director, to the Naval Hospital, Washington, D. C.

CHARLES W. RUSH, Passed Assistant Surgeon, United States steamer Colorado, granted sick leave for three months.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, January 7th:* New York Academy of Sciences (Section in Biology); Medico-Chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica (N. Y.) Medical Library Association.

Tuesday, January 8th: New York Surgical Society (private); East River Medical Association (annual—private); Medical Societies of the Counties of Chautauque, Chenango (annual), Clinton (annual), Delaware, Erie (annual), Genesee, Jefferson (annual), Livingston, Madison, Oneida, Ontario, Oswego, Rensselaer (annual), St. Lawrence (annual), Schoenectady (annual), Schuyler (annual), Steuben, Tioga (annual), Ulster, Wayne, and Yates, N. Y.; Jersey City Pathological Society; Newark (N. J.) Medical Association (annual—private); Trenton (N. J.) Medical Association (private).

Wednesday, January 9th: New York Pathological Society (annual); American Microscopical Society of the City of New York; Tri-States Medical Association (New York, Pennsylvania, and New Jersey—Port Jervis, N. Y.); Medical Societies of the Counties of Cayuga, Dutchess (annual), and Seneca, N. Y.

Thursday, January 10th: Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society (annual); Harlem Medical Association (private); Medical Society of the County of Fulton, N. Y. (annual).

Friday, January 11th: Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y.

Saturday, January 12th: New York Medical and Surgical Society (private).

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

The annual meeting was held January 3, 1884, the President, FORDYCE BARKER, M. D., LL. D., in the chair.

ELECTION OF OFFICERS.—The minutes having been read, and the reports of the various officers and committees having been presented, the meeting proceeded to the annual election of officers. The polls were kept open one hour, at the end of which time the tellers retired to count the votes.

THE LATE DR. JAMES R. WOOD.—Dr. FRANCKE H. BOSWORTH presented to the Academy a portrait of the late Dr. Wood, and made a few remarks eulogistic of that distinguished surgeon. In accepting the portrait in behalf of the Academy, the PRESIDENT gracefully expressed his appreciation of the fitness of the gift, and of the excellence of the painting. He could assure the

donors that their generous gift would always have a place on the walls of the Academy, whether in its present quarters or in any future habitation.

Dr. FREDERIC S. DENNIS then read a MEMOIR OF DR. WOOD. [It will be published in full hereafter.]

THE LATE DR. JAMES MARION SIMS.—Dr. THOMAS ADDIS EMMET read a memoir of Dr. Sims. [See p. 1.]

REPORT OF THE TELLERS.—The tellers then reported the result of the election as follows:

For Vice-President: Whole number of votes cast, 143; for Dr. ROBERT F. WEIR, 101; for Dr. HENRY D. NOYES, 42.

For Member of the Board of Trustees: Whole number, 144; for Dr. CORNELIUS R. AGNEW, 101; for Dr. SAMUEL S. PUEPPE, 43.

For Treasurer of the Board of Trustees: Whole number, 145; for Dr. FREDERICK A. CASTLE, 101; for Dr. JOHN H. HIXTON, 44.

For Member of the Committee on Admissions: Whole number, 143; for Dr. DANIEL LEWIS, 100; for Dr. EDWARD H. JANES, 43.

For Member of the Committee on Ethics: Whole number, 141; for Dr. C. DIXON VARLEY, 106; for Dr. FRANCIS V. WHITE, 35.

For Member of the Committee on Education: Whole number, 144; for Dr. W. GILL WYLIE, 106; for Dr. JOHN SHRADY, 38.

For Member of the Committee on the Library: Whole number, 145; for Dr. ABRAHAM JACOBI, 101; for Dr. HENRY D. NICOLL, 44.

Dr. Weir, Dr. Agnew, Dr. Castle, Dr. Lewis, Dr. Varley, Dr. Wylie, and Dr. Jacobi were therefore declared elected to the respective offices for which they were candidates.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS.

A STATED meeting was held December 27, 1883, Dr. A. S. HUNTER, President, in the chair.

Dr. A. S. HUNTER, President, and Dr. H. GRISWOLD, Secretary, were re-elected to office for the coming year.

Puerperal Fever.—Dr. E. L. PARTRIDGE read a paper on this subject. [See page 9.]

Dr. JOHN C. PETERS would start the discussion by saying a few words regarding the value of different agents as antiseptics. Dr. Roof had mentioned Listerine, which he had used with some apparent benefit. Dr. Peters said that this agent was composed of certain of the essential oils, that of wintergreen, etc., which were known to possess antiseptic properties. It was seldom that one had opportunity to listen to a paper which was so compact, complete, and perfectly clear, leaving but little to be added. Of course, there was much conflict of opinion with regard to the management of these cases. He believed that calomel, carbolic acid, quinine, camphor, and a number of other so-called antiseptics should not be employed in the sick room as germicides. Experiments which had been made on micrococci went to show that bacteria would live in carbolic acid in quite strong solution; the same was true of opium, nuxvomica, chloral, and quinine. But when we came to the acids—nitric, sulphuric, muriatic, and even tartaric acid—they would all destroy bacteria in largely diluted solutions. The best germicide, however, was bichloride of mercury, which would destroy bacteria when mixed one part with twenty thousand of water. Of course, it could be employed in much stronger solution. Turpentine was an efficient germicide.

Dr. P. F. MUNDÉ said that he could not see much in the paper which he could take exception to; in fact, nothing. Per-

happens one or two facts had been omitted which he would have included, but the paper was intended to be brief, and could not be expected to cover the entire ground. There was possibly one cause for puerperal fever which might be mentioned, but which was difficult to define. He had always taken the ground assumed by Dr. Thomas in a paper recently read before the Academy of Medicine, that puerperal fever was puerperal septicæmia; that it was due to the absorption of septic, decomposing, putrid matter somewhere in the genital tract. But he must say that, notwithstanding a strong desire to believe in this theory alone as to the cause of puerperal fever, he could not help leaning a little to the view entertained by some, that puerperal fever might be a disease by itself. In looking back over an experience of years, he could recall epidemics of the disease in which many patients presented no signs, either during life or at the autopsy, pointing to septic absorption. We could not say that there was no other than the septic form of puerperal fever simply because the etiology of that other form was at present hidden from view.

He believed that neither Dr. Partridge nor Dr. Thomas had mentioned exactly the indications for intra-uterine injections. It would not do to say that every time there was a rise of temperature or a fetid discharge in puerperal cases we should wash out the uterus. It happened, when he read Dr. Thomas's paper, that he had a baby under observation only two days old, and the mother's temperature had gone up to 102.5° F.; the pulse was 120. Having just read Dr. Thomas's paper, he became worried, thinking of the advisability of washing out the uterus in every case in which the temperature rose above a certain degree. It struck him that this might be the temperature of lactation, and so it turned out to be. At all events, it went down again, no intra-uterine injection having been made. The next evening the temperature again arose to 103° F. Aconite and quinine were administered, and it went down again. It seemed to Dr. Mundé that the impression should not be given that every time the temperature rose to 101° or 102° the uterus should be washed out. A mere rise of temperature did not call for injections. There should be other symptoms conjoined with elevation of the temperature, such as fetid lochia, a chill, etc. But there might be entire absence of lochia, and still there might be the best reasons for intra-uterine injections. For instance, in a certain case there were no lochia, and the nurse said the patient had had a chill. The uterus was found sharply anteverted, which condition it had probably been in since delivery; the lochia could not escape. The flexion being reduced, the putrid lochia found exit, and, after washing out the uterus, the temperature went down. Putrid lochia were not alone a sufficient indication for washing out the uterus. He regarded those cases in which there was no lochial discharge, the temperature rising to 103° or 105° F., and the pulse to 120, as the worst cases of puerperal fever, and likely to end fatally.

As to the method of making the uterine injection, he did not think it safe to employ the Davidson syringe; he used only the fountain syringe. In a certain case the nurse had attempted only to make a vaginal injection with the Davidson syringe, yet the fluid seemed to have been forced into the uterine cavity, and the patient was almost in *articulo mortis* when he arrived. The Chamberlain tube or an elastic catheter could be used for making the injection with the fountain syringe, but he did not like the terminal perforation. The cavity could be thoroughly washed out through side-openings alone, and with less risk. He believed that if the temperature did not remain permanently reduced, after using the uterine douche for twenty-four or forty-eight hours, the douche should no longer be continued. Again, when the water came away clear, and the discharges were rendered pure, there was no further necessity for the douche, and, if continued longer than necessary, it would do harm. But, so

long as the lochia remained offensive, in cases in which the douche was indicated, he would be the last person to stop the injections. Again, with regard to cases of parametritis, or in which there was inflammation in the region of the broad ligaments with exudation, there being but a local inflammation, he believed that all disturbance or irritation should be avoided, and intra-uterine injections would do harm. In cases of tedious labor he would wash out the vagina with a carbolyzed solution or with bichloride of mercury a number of times during the progress of labor, and also after the birth of the child. If the hand had been introduced into the uterus, or if there were any other indication, he would inject that organ with the carbolyzed solution, two to three per cent., and he preferred for this purpose ice-water to hot water. The latter, if used sufficiently hot, was liable to scald; if not used hot, it would not arrest hæmorrhage so well as ice-water. The latter was not complained of by the patient as being disagreeable. He also administered ergot; if the patient could not swallow, then hypodermically. He gave ergot, quinine, and strychnine for two or three weeks, until the uterus had become thoroughly involuted. He also had vaginal injections given two or three times a day after labor, until he ceased his visits.

Dr. S. BARTON said that he had put his views regarding vaginal injections after normal labor on record at the county society recently, and he wished simply to reiterate what he said on that occasion. It had been said that the genital tract after labor had undergone traumatism, and that it should be treated as an operation-wound should be treated located elsewhere. But what did we do in the latter case? We closed the wound, putting on an antiseptic dressing, then let it alone, and thus obtained good results. In making vaginal injections after normal labor we violated this rule; we disturbed the genital tract twice a day; we opened up any injured and healing surfaces; we did not close up the parts by an antiseptic dressing, as it was impossible to do so. He had already stated his somewhat extraordinary experience after commencing the use of vaginal injections as a prophylactic; he had six cases in which the injections had apparently been the cause of puerperal fever. The method had been largely abandoned in German hospitals as not being beneficial.

Dr. DANIEL BROWN had before expressed himself as opposed to washing out the vagina after normal labor. He took the ground that the woman was not necessarily torn to pieces after childbirth, was not necessarily in a septic condition, and he believed that a good deal of injury might be done in making the injections and in disturbing the patient. The vagina was not an open tract as the woman lay in bed, and there was not a rush of septic air into it. If, however, the lochia became offensive, or labor were abnormal, then he would agree, with the other speakers, that the genital canal should be washed out and disinfected. He had never obtained any results with quinine in reducing septic fever in either large or small doses.

Dr. JEWETT, of Brooklyn, had recently been making some experiments in hospital practice going to test the value of antiseptic prophylactic measures in midwifery. The number of patients was fifty. Thirteen had been under the care of his immediate predecessor, who did not practice strict antiseptic measures during his service. The remaining thirty-six were confined in wards which were first evacuated, and then thoroughly disinfected with chlorine, the windows being left open, the bed-clothing boiled, and the furniture thoroughly cleansed with an antiseptic solution. Special instructions were given the attendants regarding cleanliness, and other measures were taken against sepsis. The figures were not sufficiently large to draw positive conclusions from, but they went to show in a degree the advantage of such precautions. Of the thirteen patients

treated only with ordinary measures for cleanliness, ten had a temperature above 99.5° F. This was the highest temperature which Dr. Jewett looked upon as within the bounds of perfect safety after delivery, although Dr. Lusk gave the limit a little higher. Of the thirty-six treated with thorough antiseptic precautions, only five had a temperature above 99.5 longer than one day, and the temperature rose to that degree at any time in only six of the entire number. He had always used the vaginal douche after delivery until recently, when, making experiments as to its value, he employed it in one half the cases only, unless some special indications arose. Those in which it was not employed showed just as favorable a temperature as the others. Possibly, had other strict antiseptic precautions not been observed, the vaginal douche would have proved more necessary. He regarded the local guard placed over the vulva as important. It was rendered antiseptic by a five-per-cent. solution of carbolic acid. He had the greatest confidence in the douche as a curative measure in septic infection. He did not resort to the uterine douche until after the vaginal douche had failed to control the disease. He was fully persuaded that the vaginal douche was capable of doing injury. There was danger, for instance, of the nurse introducing septic matter during the injection. He could cite cases in which it had been the cause of puerperal fever.

Dr. PARTRIDGE, in closing the discussion, said that he would express himself regarding the vaginal douche as Dr. Mundé had done. It might do harm if improperly employed, but otherwise not. He had been in the habit of making vaginal injections twice in twenty-four hours for several days after confinement. The patient had always expressed herself as rendered comfortable thereby. He believed, with Dr. Mundé, that there was no single indication for the uterine douche.

The uterine douche need not be used so frequently if it were followed by an injection of a ten-per-cent. mixture of iodoform and glycerin. He thought the question with regard to two forms of puerperal fever, one of septic origin and another of zymotic origin, might be considered an open one. In our present state of knowledge on this point, he thought we should not attempt to be too positive in making out every case to be one of septicæmia. It was quite true that the lesion need not be a large one to admit of septic infection. In every case of labor the cervix was lacerated, at least to a slight extent.

NEW YORK NEUROLOGICAL SOCIETY.

A REGULAR meeting was held December 4, 1883, Dr. WILLIAM J. MORTON, President, in the chair.

NEUROTIC AFFECTIONS ACCOMPANYING JOINT LESIONS.—Dr. GEORGE W. JACOBY read the following paper:

The history of the subject goes back as far as Hippocrates, by whom it is mentioned. John Hunter was the next to take any note of it, and it is with him that the sympathetic theory originated. Malgaigne (1826) and, within the last ten years, Weir Mitchell, Duchenne, Verneuil, Sir James Paget, and Charcot and his pupils, comprise the list of names that have cast light upon the subject. The experiments of Valtat show conclusively that, as a result of injury to the articular or even to the periarticular tissue, produced by irritant injections, the muscles of the entire limb, but more particularly the extensors of the joint, become atrophied. The result of the experiment given in the paper, as shown by the autopsy, is that the extremity which was experimented upon lost eighty grammes in weight in twelve days, and that each and every muscle separately weighed less than its corresponding fellow of the left side.

The affections which most frequently follow joint disorders are paralysis and atrophy of the muscles, and hyperplasia of the

subcutaneous connective tissues. More uncommon are anæsthesia, hyperæsthesia, analgesia, hyperalgesia, and neuralgias. Three groups of nerve functions are implicated—motility, sensation, and nutrition.

Symptoms.—After the joint lesion, there is a change in the appearance of the limb. The extensor muscles are generally the ones involved. There is a change in the electrical reaction of the muscles; their contractile power is diminished, and finally lost. There is no reaction of nerve degeneration, no reversal of the normal contraction formula. This is also most noticeable in the extensors. The paralysis may appear as early as twenty-four hours after the accident; it may also appear very late. The hypertrophy of subcutaneous connective tissue seems to stand in a direct ratio to the atrophy of muscular substance. The atrophy is ascending and progressive. Contracture is rare. The disorders of sensation are early symptoms, and the differential diagnosis between these affections and progressive muscular atrophy may become difficult.

The conclusions which I am entitled to draw from the notes of thirty cases are: 1. That in all cases, except those involving the ankle or wrist joint, the muscles affected were the extensors of the diseased articulation. 2. That, in those cases which involve the ankle or wrist joint, the affection is descending instead of ascending, and that the extensors are not affected to any greater extent than the other muscles. 3. That, in cases of arthritis of any of the joints of the fingers, the interossei muscles suffered first and most.

The cases which present particular interest are the following:

CASE I.—Mrs. L., aged twenty-four, while walking, slipped and fell striking her right knee. The joint rapidly increased in size and was very painful. The following day it was very much enlarged, the patella pushed forward, and fluctuation was distinctly noticeable. The joint affection improved rapidly, but upon the seventh day a distinct paralysis was noticeable. The movement of flexion of the leg upon the thigh was easily executed, but that of extension was performed with great difficulty. Patient could only by the strongest effort produce any contraction of the triceps cruris. As the effusion became absorbed the paralysis increased, and at the end of three weeks it was impossible for her to extend the leg at all. Atrophy was now well marked, showing a difference of three centimetres in favor of the healthy limb. The gluteal muscles were also involved. The electro-contraction of the muscles were decreased to both currents.

CASE II.—This case shows how soon after the injury paralysis and atrophy may ensue. Patient, a laborer, aged thirty-four, was struck upon the left knee on a Friday afternoon. He applied ice to the joint. The swelling went down. I saw him upon the following Monday, seventy-two hours after the injury, and then a distinct paralysis of the triceps cruris was noticeable, and atrophy was distinguishable upon the following Friday.

CASE III.—By this case may be seen how entirely disproportionate the effect may be to the cause. Patient, L. H., merchant, aged thirty. While walking, his left ankle joint turned, the outer margin resting upon the ground. Notwithstanding severe pain, he continued his walk. Used the joint for several hours. When he examined his foot he did not notice any change in the appearance, but it was painful on pressure. After two months he noticed a slight weakness in the injured leg, which was particularly observable upon going down stairs. Four months after the accident I saw him. His condition was then as follows: His foot hangs with the toes pointing downward, and can not be brought to a right angle with the leg. He walks upon his toes, and does not bring his heel to the ground. The toes may be easily raised, but they fall back again by their own weight. The interossei muscles of the foot are atrophied. The peroneal muscles and those of the thigh are also involved. The gluteus maximus is evidently considerably atrophied, for a large depression takes the place of its former prominence. Added to this, severe neuralgia of the sciatic and peroneal nerves rendered his condition almost unendurable.

The pathogenesis of the affection is still a disputed one. The sympathetic of Hunter, the pressure theory of various writers, the theory of functional inertia, then that of Vulpian, which is reflex, and, finally, those of Decosse and Charcot, are all incapable of satisfactorily explaining all of the cases.

The treatment, in order to be successful, must be varied and adapted to each special case. The chief agents at our disposal are electricity, massage, mechanotherapeutics and hydrotherapeutics in the form of hot and cold douches. Massage, in very many cases, seems to deserve preference to the electrical currents. The effects producible by massage are:

1. The diffusion of any articular effusion; 2. The diminution of vegetation; 3. The loosening and destruction of adhesion; 4. Increase of circulation; 5. Stimulation of muscular fibers.

In fact, all the agents above mentioned seem to act similarly by stimulating the nutrition of the affected muscles, by increasing the flow of blood to the parts, and perhaps thus causing a reflex excitability of the motor tracts.

Dr. CHARLES F. TAYLOR said the subject was one with which he was familiar, as all persons engaged in the treatment of joint affections must be, but it was too large even to touch upon, in many of its aspects, in the limited time at his disposal. He was obliged to differ with the essayist, both as to the pathology and as to the treatment of the neurotic disturbances attending or following joint diseases of the character which he had set forth in the paper. In regard to the pathogenesis, he did not think it necessary to adopt any peculiar theory, or to assume that even any special deviation from the ordinary course of nerve function took place, in order to account for all the facts observed in these cases. The difference was one of degree only. A person was attacked with inflammation of the knee joint, for instance. This was rapidly followed by diminished size of the muscles controlling the action of that joint, with diminution and sometimes even entire loss of muscular action. But loss of muscular action was by no means evidence of loss of muscular power. The nerve-centers were unquestionably affected, but the cerebral nerve-centers were the seat of the greatest disturbance. No theory could be adequate which left the cerebral nerve-centers out of account, and the consequent mental element, which played, in his opinion, so important a part in these cases. The simple loss of muscular action, consequent on an attack of inflammation of the knee joint, was sufficient to account for an immediate diminution of the size of the muscles whose freedom was curtailed. This was the certain result of mechanical restraint alone. But, if, besides the mechanical restraint of position or retaining apparatus, there were added the mental restraint of fear, the difference in the rate and amount of muscular atrophy was enormously increased. Mental restraint acted like an Esmarch's bandage: it squeezed the very life out of a muscle. As a very simple proof of the remarkable effect of mental restraint in causing muscular atrophy, he would mention those frequent instances accompanying disease of the hip joint. These patients often applied with limbs attenuated to the last degree. That a large portion of the muscular attenuation accompanying somewhat long-standing hip-joint disease was due to the mental restraint of motion, which might cause suffering, was proved by the fact that the application of proper mechanical protection, by which the mind was relieved of the fear of pain, was followed by immediate increase of muscular growth. This was so common and well-known a fact that advantage was constantly taken of it in the management of cases. His observation of the effects of joint diseases on the muscles must have included some thousands of cases, and he had never seen a case of atrophy which, in his opinion, could not be perfectly explained by non-use and mental restraint.

In regard to the therapeutics of muscular atrophy and loss of action following joint disease, he feared he must differ with the essayist quite as widely as in regard to their pathogenesis. So far as the muscular wasting had been caused by non-use, during the progress of the arthritis, it was sufficient to set the muscles to work again after the inflammation had subsided. Muscles stubbornly refused to act, or, if forced to act, they as stubbornly refused to develop, during the progress of an arthritis. We must wait till the joint was well before we could expect the muscles to act readily. It was astonishing to notice how deep and lasting the impressions made on the cerebral nerve-centers sometimes were. Whatever the treatment might be, he did not believe it could be of any direct service so long as a mental restraint over the muscles was continued; and it was equally true that whatever would remove such mental restraint would cure the atrophy. So important did we consider the mental influence over the muscles, attending and following joint diseases, that we took special pains to get and to keep the direction of that influence, for the very purpose of hastening the recovery of the muscular power, after curing the joint disease. But the object of treatment should be to divert the mind from the affected member, rather than to keep up attention to it, by local treatment. It was true that massage would sometimes seem to do much good to the atrophied muscles; but this was apparent and indirect rather than real and direct. Massage had elements of mental diversion and control which might be properly and usefully employed. But, with a large experience in its use, he was free to say that he thought it was very much overestimated as a direct therapeutic agent. Its direct effect on the muscles was very slight, and what there was was not exercised. Exercise involved nerve action as the initial force. Massage merely assumed to promote the forward displacement of a certain small portion of the tissue fluids. But such propulsion of the fluids contained in the soft parts, even if effected, was not exercise, nor a rational substitute for exercise. Only by the legitimate use of the nerve-centers, especially of the cerebral nerve-centers, could there be any action deserving the name of exercise. To regulate such nerve-center function, when disturbed by the strong impressions made by joint inflammations, was the indication presented in the cases under discussion. In most cases time alone was sufficient. In others, any means which effected a diversion of attention, whether applied to the affected member or at a distance from it (which was the safer plan), would effect a cure. Incidentally, massage, electricity, the manipulations of the so-called "bone-setters," as well as the "animal magnetism" of the more arrant quacks, all did appear to produce wonderful results in a certain number of cases. The results were real, but were not produced through any direct effect on the parts, but through the incidental impressions made on the cerebral nerve-centers; in other words, on the mind. The worst of it was that there was a large number of cases in which direct treatment of the part affected by the mental restraint tended to increase the mental impression, and to indefinitely postpone that unrestrained action of the muscles by which alone they could regain their power. The most difficult cases within his experience had been those in which the patients had had their attention to the affected member kept up by too much local treatment after the joint inflammation had passed away.

Dr. LEONARD WEBER had seen some cases of muscular atrophy following joint disease, and remembered one in particular, which might be of interest to the society:

Mr. J. W., aged thirty-two, merchant, of nervous temperament, but strong and active, made a tour through Switzerland in the summer of 1879. Being a good pedestrian, he traveled mostly on foot, but, after a severe Alpine tramp in the upper Engadine, he was taken with synovitis

of the knee joint. When the effusion had passed away, the extensor muscle above the knee had wasted considerably; the patient was unable to walk, and reached New York with difficulty. On examination, the joint was found to be in good order again, but the atrophy of the extensor muscle was still very marked, and the patient, by the support of a cane, walked, but not without difficulty. A four weeks' course of faradization made no appreciable change, and, although he was assured that he would regain the use of his limb completely in the course of time, he was not satisfied, but grew despondent, and finally left for Europe to consult Professor Erb. The latter told him the paralysis was not in his limb, but in his mind; that he should go about and exercise and live well, and he would soon regain the full use of his muscles. He followed this advice, and returned to New York early in the spring of 1880, in perfect health.

As to the pathogenesis of the disorder, Dr. Weber believed that the muscular paresis and atrophy in the case reported, and in others of a like character, were of reflex origin, and that functional disturbances of motor centers in the brain, and not in the spine, were probably the cause of the trouble. Of massage and its effect in such cases, as reported by the author of the paper, he had had no personal experience, but had seen excellent results from its proper application in subacute joint diseases, muscular rheumatism, and bad sprains.

Dr. E. C. WENIG said that the paper had brought out several points of interest, especially as regarded aetiology, symptoms, and the hopefulness of treatment. He was sorry to find, however, that the reader had nothing new to offer in explanation of the pathogenesis of these conditions. Admitting the correctness of Sappey's views concerning the richness of the articular and periarticular tissues in nerves, it certainly seemed thoroughly puzzling why acute polyarticular rheumatism was not more frequently followed by just such accidents as Dr. Jacoby had described. Again, those more chronic joint manifestations dependent upon the gouty diathesis, where profound structural alterations were frequently observed, only quite exceptionally led to atrophy, paralysis, and the other neurotic disturbances alluded to. Upon these points he was sorry to find that the paper under discussion left us as much in the dark as we had been before.

With regard to massage, although his experience was limited, it was yet sufficient to fully convince him of its utility in certain cases. Of course, there was massage and massage. But, when properly and systematically applied, it was useless to try now to dispute its beneficial action. The combined experience of a large number of competent men placed its usefulness beyond the pale of doubt.

Dr. C. HEITZMAN said: "When I was a student in Vienna, a girl, twenty-five years of age, fell down stairs and acquired serous gonitis, after which she was paralyzed and confined to her bed for five years. She was sent to a water-cure. A physician there urged her to walk, in order to enable him to judge about the degree of the disease, but she began crying, and said she was unable. She went home in despair. Her sister asked her to make at least an effort to walk. After considerable urging, she got out of bed and walked. This illustrates that mental influence has much to do with these affections.

"I would call the attention of Dr. Jacoby to an article by Dr. Nicoladoni, published in 1871, in the 'Wiener med. Jahrbücher.'" I have seen his specimens with the nerves brought out by the use of chloride of gold, and, from my observation, I am convinced that these terminal nerve-fibers are not stable and unchangeable formations, but, on the contrary, that new nerve-fibers may form at any time of life from the living matter present in all tissues.

"I am thoroughly convinced that nerves may disappear and appear, according to certain physiological necessities, certain

physical conditions, of the body, such as, for instance, are results of exercise.

"In an inflammation of a joint, the synovial and capsular wall being the seat of pathological changes, of breaking down of tissue, certain nerve-fibers of the sensitive sphere will be within its range, and we should know that a certain number of them perish altogether.

"Dr. Jacoby to-night did not give a theory of his own, but he quoted various authors. It certainly was the best plan for him to pursue, as so very little is known, even in our day, about nervous action.

"We know that, by the inflammatory destruction of a number of sensitive nerve-fibers in the capsule of the joint, at once three spheres are involved: the motor, for there is paresis or paralysis; the sensory, for there is pain; and the vaso-motor or trophic, for there is emaciation.

"So far as my insight goes, I am convinced that the living matter in a reticular arrangement produces the gray matter and all essential portions of nerves, including the axis-cylinder. This fact is thoroughly acknowledged by Professor Stricker, of Vienna.

"There may be a loss of living matter of certain nerves, in consequence of inflammation, and loss of contractility, with impaired conduction toward the center. We then have comparative rest in a limited portion of the spinal cord, or even the brain, for the reticulum of living matter is set at rest for a time, without there being a material change in the living matter of the gray substance and ganglionic elements.

"If massage will re-establish the activity of muscles, we are prepared to understand that the field in the spinal cord before out of action may at once be brought into motion, and the motion communicated at once to the motor ganglia and all the sympathetic centers which are situated along the spinal cord, as physiologists agree.

"The nervous action may for a certain time be impaired or dulled, because the reticulum of living matter is in comparative rest, lacking an impulse from without. So soon as such an impulse is carried to the resting portion, either by mental action, energetic will, or mechanical shock, as is done in massage, or in any other way, the contraction of the living reticulum is induced, and the normal condition re-established. Neither the assumption of centripetal neuritis, nor the theory of reflex action, can explain the phenomena observed after the inflammation of articulations and their occasional speedy cure."

Dr. HENRY L. TAYLOR said: "I can contribute a case showing the beneficial effect of the use of the body battery:

"A woman, under the care of Dr. J. West Roosevelt, at the Roosevelt Hospital Dispensary, of middle age and neurotic personal and family history, presented among other symptoms that of a pricking sensation down the right arm and in the right hand. There was no joint trouble. Dr. Roosevelt and myself regarded it as one of the neurotic disturbances incident to a person of her temperament. The body battery was tried for its psychical effect, and the woman returned in two days, with the abnormal sensations gone. The symptoms had lasted a considerable time. The same treatment was applied to the hand, without effect, during the week which she has since been under observation.

"I regard the result in this case as entirely due to mental influence.

"Before concluding my remarks, I wish to speak of an interesting class of cases alluded to by Dr. Gibney—the pseud-arthroses. We have in these cases nearly or quite all the symptoms enumerated by Dr. Jacoby in his paper—atrophy, hyperæsthesia, or anæsthesia, etc., following mental restraint, there being no affections of the joints. I regard the trouble as functional and seated mainly in the brain, and not in the spinal cord, as Dr. Gibney believes, if I understand him. Almost any-

thing calculated to make a profound impression on the higher nerve-centers will often prove curative in these cases. This is, in my opinion, one of the most important effects of massage.

"I have in mind three cases of ankle trouble following sprains, seen three to five months after the injury. The acute symptoms had subsided, but pain, tenderness, and such impaired function as to cause limping, persisted. These patients had been treated with supports, etc., for several months. Physical examination showed no local trouble not readily explained by mental inhibition. There had been recovery from the sprain, without a corresponding readjustment of the nerve-centers to the new condition. The patients were perfectly and rapidly cured by purely psychical treatment. I do not doubt that massage often accomplishes the same result through its psychical effects in similar cases, but it is an empirical method, as generally employed."

Dr. HENRY J. GARRIGUES said: "What little experience I have had with massage is in its favor, but that is almost nothing compared with that of Dr. Taylor. Nevertheless, I have used massage for ten or twelve years. I became acquainted with it when it was quite new, and have found it most excellent for secondary conditions and for the affection to which Dr. Jacoby alludes."

The PRESIDENT said: "I will say a few words upon the subject of the continuous body battery and its use; the battery consists of a simple pair of elements. I well recollect a case in which I used this with good effect. A gentleman came to me with chronic arthritis. Associated with it was paralysis of the extensor group of muscles; the foot was dropped and the toe dragged; he said no form of electricity that he had tried had done him any good. I told him that I would give him a battery which he could wear all the time, which consisted of pieces of silver and zinc connected by copper wire. The zinc was shifted about upon different parts of the body, and a constant current was kept up, which could be tested at any time with ordinary litmus paper. While he was under alkaline treatment the battery worked with better results, the excretions being saline."

"This battery is also useful in the treatment of chronic ulcers. The granulations formed will be found much more healthy. It is also beneficial in chronic eczema."

This much he would add to the practical part of the paper, since the main question, after all, was as to treatment.

Dr. V. P. GRANEY said that at times it was very difficult to determine whether the atrophy preceded or followed joint disease. It was his opinion that it was more frequently the accompaniment of epiphyseal disease than of joint disease proper, and he wished to emphasize the fact—for a fact it was, according to his observations—that the majority of grave lesions about joints in childhood were epiphyseal—in other words, chronic epiphysitis.

Synovial disease he believed to be rare. If one examined a hip, for instance, said to be the subject of disease, marked atrophy was usually found in the thigh and calf muscles long before any pronounced joint symptoms were present. The atrophy, he further stated, was confined to the muscles and not to the bony tissue, for it was a rule that in chronic epiphysitis, about the knee for instance, the epiphysis was actually elongated. He, in common with many other orthopedists, had long regarded acute atrophy as one of the most constant signs of chronic articular ositis, and he believed the atrophy to be purely reflex and not the result of disease, or of the pressure from apparatus or bandages.

One argument brought against mechanical treatment—viz., that atrophy was produced—was fallacious. The clinical history proved this conclusively. He was not sure whether chronic

synovitis induced atrophy, but he was positive that in acute synovitis atrophy was rather the exception than the rule.

A class of cases presented certain neuroses which were very valuable in excluding bone or joint disease. They were known as spinal pseudo-arthritis, and known, furthermore, as neuroses of the joint, neuro-mimosis, hysterical joint, Brodie joint, etc. The neuroses referred to were neuralgia, hyperæsthesia, anæsthesia, but rarely any atrophy. He believed that they had their origin in the spinal cord and the meninges, and the readiness with which they responded to treatment confirmed him in his belief.

Furthermore, the neuralgia of chronic articular ositis of the hip was well known, and the knee branch of the obturator never was affected early, and very often late in the disease, although this was denied by some writers, and especially a recent writer, Dr. Clippingdale.

In some of the most advanced cases of caries of the hip this obturator neuralgia was very distressing. Very frequently the sciatic nerve was involved, and in some cases the sciatica was most intense, and yielded to treatment with great difficulty.

The theory of paralysis and degenerative nerve changes being sequences of chronic arthritis was one about which he did not feel fully convinced. He referred to a case of chronic arthritis of the knee, in an old woman who had paralysis of most of the muscles of the thigh and leg, in which it was thought by some who saw the case that the paralysis was dependent on the joint lesions, but the proof was not by any means conclusive.

Dr. JACOBY said: "The first point to which I desire to reply is that brought forward by Dr. Taylor. He said that he believed these nervous changes, particularly the paralysis and atrophy, were produced by psychical or mental influence, and that they might be relieved by attention to this point. I am at considerable variance with him as regards the effect that mental influence has in the production of these disturbances. I, for my part, can not understand how mental uneasiness can produce an atrophy, which is easily diagnosticated with the tape, of a certain muscle, and that in the short space of three days. But, as the doctor has promised us a paper upon this subject, perhaps that will succeed in convincing me."

"As regards the opposition which the massage treatment has received, I expected it would receive more. Massage has, especially in the United States, been very much in the hands of non-professional men, and, consequently, has been greatly abused and misapplied, but I hardly think there can be any question as to its efficacy in suitable cases and when properly applied."

"The theory advanced by Dr. Heitzman is very similar to that of Professor Charcot, who, as I mentioned in the paper, believes that certain parts of the cord are in a state of inertia or stupor."

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of October 17, 1883.

DOWNWARD DISPLACEMENT OF THE TRANSVERSE COLON; THREE CASES, WITH AUTOPSIES.—Dr. CHARLES HERMON THOMAS read the following paper: A deformity of the transverse colon, consisting in the elongation of that portion of the large intestine and its displacement downward in the form of a loop or festoon, has been observed by me in three instances in private practice. Autopsies were had in them all. In the first the most dependent portion of the gut was found midway between the umbilicus and the pubic symphysis; in the second it was deeply impacted in the cavity of the pelvis; and in the third it reached the level of the umbilicus.

A positive diagnosis was not made in any of the cases, although in two of them the striking clinical conditions present

were studied with special care in association with experienced and highly skilled observers. In the second in order of occurrence the relationship between it and the preceding one suddenly occurred to my mind, and was communicated to the operator while on our way to make the post-mortem examination. In the third case the actual condition present was strongly suspected before death. So that, in both of these latter, special precaution was used at the autopsies to avoid disturbing the relative position of the abdominal viscera until their location had been accurately determined.

The lesion here described seems to be of rare occurrence. Thus far I have failed to discover a single recorded case; and not until this paper was nearly completed was I able to find any published reference to the condition, however vague. Several months ago I asked the assistance of Dr. Formad, who informed me that in a series of autopsies, numbering over two thousand, which he had made, he had not observed an instance of like character. He has also kindly sent me the following note:

"UNIVERSITY OF PENNSYLVANIA, December 15, 1882.

"DEAR DR. THOMAS: . . . I looked very thoroughly through the literature of intestinal lesions, but did not meet any record of misplacement of the transverse colon.

"Very truly yours,

"H. F. FORMAD."

CASE I.—Male, aged eighty years, a retired gentleman, came under my care August, 1874, as a patient of Dr. J. J. Levick, who had placed his practice in my charge during his vacation, and who informs me that there was no previous history of abdominal disease.

The symptoms present were extreme emaciation, feebleness, anorexia, and a profuse but fitful diarrhœa. The abdomen was retracted, and somewhat tender upon pressure. There was no complaint of pain except at intervals of three or four hours, when the diarrhœa had ceased for a time. Coincidentally with the cessation of the diarrhœa, a tumor about five inches long and two inches wide, of firm consistence, and visible on inspection, appeared beneath the thinned abdominal walls in a transverse position midway between the umbilicus and the symphysis pubis. The tumor persisted but an hour or so at a time, disappearing immediately upon the return of the diarrhœa. During the periods of continuance of the tumor the pain was so severe as to rapidly weaken the patient. This condition of alternate flux and painful tumefaction was repeated several times daily until death took place. During the attendance upon the case there were associated with me Dr. Albert H. Smith and a distinguished physician from another city—a near relative of the patient. With attention fully directed toward it, and after repeated observations, we were unable to frame a reasonable hypothesis as to the exact character and origin of the tumor. Death occurred September 12th, about three weeks from date of attack.

Autopsy.—In the presence of Dr. Levick and the relative mentioned, I made the abdominal section. To the former I am especially indebted for the specimen obtained, and which is still preserved.

Upon laying open the abdominal cavity, the transverse colon was found to be greatly elongated and proportionately narrowed, the loculi being nearly obliterated, forming a loop open at the top similar to the letter U, the most dependent portion occupying the position of and constituting the tumor as above described, i. e., the horizontal portion of the loop rested upon the small intestines, midway between the umbilicus and the pubic symphysis.

CASE II.—Female, aged fifty-four years, a lady of delicate frame and refined habits of life, was under my charge for about ten months prior to her decease. During the greater portion of this period Dr. James H. Hutchinson was associated with me in the attendance. Dr. Charles K. Mills also saw her for me during my vacation. The patient had previously been attended by a homœopathic practitioner, who had diagnosed her condition as enlargement of the liver and stricture of the rectum. The latter supposed condition he had treated by the introduction of rectal bougies, this practice being afterward abandoned on account of the pain produced, and the lack of beneficial results.

Profound cerebrastrhenia from other causes, with several months of delirium, and which finally led to a fatal result, served greatly to complicate the issues involved. The abdominal conditions which had been recognized from the beginning were thus either masked or placed entirely in abeyance during much of the time.

The more prominent symptoms recognized were (1) pain, referred chiefly to the region of the liver, and extending both upward and downward, which pain was aggravated by walking, and was described as of a dragging, tearing character, and which had existed for four years or more. It was very much relieved by the recumbent posture, and, after some months spent mostly in bed, almost entirely vanished.

2. Obstinate constipation, with indications of obstruction, even a liquid passage being voided with difficulty. The capacity of the rectum to retain enemata was also diminished to two ounces.

3. Two solid tumors, elongated in form and of the consistency of solid faeces, were discovered, located one on each side of the abdomen, and evidently just beneath the parietal structures. They were vertical in position, and about eight inches distant from and so parallel to each other, and were traced from the border of the ribs to within about two inches of the pelvic brim. This condition was observed but a few times, and at considerable intervals; at other times it was absent. The hypothesis was adopted that these masses were the ascending and descending colon, respectively, in a state of fecal impaction.

Death occurred March 30, 1882, supervening upon a severe mental shock. An autopsy was made by Dr. William M. Gray two days later, Dr. Hutchinson and myself being present. To quote from Dr. Gray's notes: "Upon opening the abdomen, found complete prolapse of the transverse colon. It was carried beneath the pubes and rested on the bladder. The large intestine was much narrowed, and was filled throughout with hard nodulated faeces; the mesocolon was absent, and the omentum, which was free from fat, was extremely atrophied; the rectum was normal, showing no evidence of stricture; the liver was of normal size, but, upon microscopic examination, showed marked cirrhosis."

Thus, that which had appeared to be the ascending colon proved to be the descending limb of the displaced transverse colon; and that which had seemed to be the descending colon was shown to be the ascending limb of the same malformation.

The pain which had previously been felt in the region of the liver, and which had been relieved by recumbency, had manifestly been caused by the sharp flexure of the colon contiguous to it; and the rectal obstruction by the crowded condition of the pelvis produced by the invading loop of large intestine.

CASE III.—Male, aged thirty years, a tailor's cutter, under attendance nine days prior to decease. The subject of advanced Bright's disease, with "hyaline, epithelial, and granular tube casts, also mucous cells, compound granule cells, and free oil globules," he was extremely exhausted thereby. He also complained of severe pain in the abdomen to the right of and slightly above the level of the umbilicus. Upon inspection and palpation of the part, no enlargement or induration was discovered; but light percussion developed an intensely tympanitic sound confined to the region described. Misplacement of the transverse colon was suspected, and the region kept under observation for any evidences of fecal impaction which might, but which did not, present. Death occurred suddenly March 19, 1883. Autopsy two days later, by Dr. W. M. Gray, operator, Dr. W. H. Burke and myself being present.

The following notes were made by Dr. Burke: . . . "Body rather emaciated, and showing signs of commencing decomposition. On opening abdomen, absence of fat noted, omentum normal. Peritoneum showing traces of lymph and pus, in the pelvic region especially, but no general inflammation. Transverse colon empty, distended with gas, and has a sharp flexure at its center, bending obliquely downward and toward the right, to the level of the umbilicus, thence sharply upward to its normal position. Mesocolon intact and apparently normal except in length. No sign of fecal obstruction at the point of flexure. Both kidneys cirrhotic; capsule adherent, and secreting structure destroyed."

Evidently the heightened tympany localized near the umbilicus,

which had been previously recognized and ascribed to the presence there of a portion of the transverse colon misplaced, had in reality been so caused.

No adhesions of the displaced parts were found in any of the cases cited. The intestinal fault was probably not the cause of death in any of them. Taking them together, it will be seen that clinical conditions and post-mortem appearances agree in at least one important particular, viz.: the location of the displaced intestine in contact with the anterior abdominal wall and below its normal site.

The normal anatomical relations of the colon have a special significance in the light of these cases, from a diagnostic point of view. The ascending and descending portions of the colon are, normally, to be found in contact with the *posterior* or lumbar wall of the abdominal cavity—behind the small intestines—and are there bound closely down by reflections of the peritoneum. The transverse colon, on the contrary, is normally in contact with the *anterior* abdominal wall—in front of the small intestines—where it is loosely suspended by the transverse mesocolon, a structure of considerable length.

It therefore appears to be a practical impossibility for the vertical portions of the large intestine to become spontaneously misplaced anteriorly. But of the transverse colon, its displacement downward—in which changed position its relation of contact with the anterior abdominal wall is retained—these cases show to be a condition of repeated occurrence.

Conclusions.—1. Displacement of the transverse colon downward within the abdomen may be, to any degree, partial or complete.

2. Such displacement will present as solid tumor if the bowel be in a state of fecal impaction, or as a limited area of heightened resonance if the bowel be distended with gas; but in either case the displaced part is to be found *in contact with the anterior abdominal wall.*

3. The occurrence of intra-abdominal tumor situated below the normal site of the transverse colon, and having the same general configuration as the colon, such tumor being of a certain consistence, and presenting evidences of being in contact with the anterior abdominal wall, or the occurrence of areas of special tympany with like outlines and similarly located, constitutes a diagnostic sign strongly indicative of downward displacement of the transverse colon.

Meeting of December 12, 1883.

SOME NEW FACTS ABOUT ASTIGMATISM.—DR. M. LANDESBERG read the following paper:

Astigmatism is such an abstruse subject that it should generally only be treated before the narrower circle of physicians who have made ophthalmology a special study. And, if I beg leave to lay before you the results of my observations in regular astigmatism, there must be some special reason which induces me to make exception to the rule. The results of my observations open a new insight into the nature of astigmatism; they mark a real progress in the knowledge of the latter, and furnish practical consequences which may be utilized for the benefit of all those who are suffering from a similar trouble.

You know, gentlemen, that by astigmatism we understand that form of asymmetry of the cornea in which the curvature of the latter is either different in the different segments of the same meridian, or in the different meridional planes. The first form is called *irregular*, the latter *regular astigmatism*. Irregular astigmatism may be either acquired or congenital. It is very often associated with irregularities of curvature in the lens, and but very seldom admits of any remedial help, or of correction by glasses.

It has been the scientific dogma of our days that regular astigmatism presents, in the greater majority of cases, a congenital and unchangeable optical defect of the cornea, which can only be neutralized by the selection of suitable glasses. The development of regular astigmatism post partum is considered to be of very rare occurrence, and to take place only in consequence of certain affections of the cornea, of spasm of the lids, and occasionally after iridectomy and extraction of cataract. In these instances, however, astigmatism is temporary only, and it generally subsides when the causal affection which had produced the changes in the curvature of the cornea has been removed.

My observations in regular astigmatism are in full contradiction to the prevalent opinion concerning the nature of this form of error of refraction. They have taught me that, certain conditions given, regular astigmatism may develop in any cornea; that it is apt to progress and to increase in degree when the primary cause, of which astigmatism is only the effect—one of the many symptoms only of the morbid process in which the eye actually is involved—continues to work. If you have such a case in hand, and you correct the optical defect by cylindrical glasses, you only add a new injury to the existing ones; you only aggravate the morbid process; you consolidate a disorder which is apt to be cured by appropriate treatment.

The conditions under which regular astigmatism may develop are: *Progressive myopia, with and without spasm of accommodation; spasm of accommodation in an emmetropic, myopic, and hyperopic eye.*

In my first communication on this subject, in von Graefe's "Archiv für Ophthalmologie," xxvii, 2, I gave the history of fourteen cases which had come under my treatment, either for progressive myopia with and without spasm of accommodation, or for the most various asthenopic troubles, based upon spasm of the ciliary muscle, in connection with myopia or hyperopia. All these cases were complicated with regular astigmatism. The degree of the latter varied from 1-36 to 1-10. An increase in the degree of astigmatism was observed in two cases of progressive myopia, in connection with the progress of the latter. The treatment instituted for the asthenopic disorders, or for the progressive myopia, had the effect not only to cure the affection proper, but also to remove astigmatism entirely. The degree of astigmatism gradually subsided, keeping pace with the decrease of the other morbid symptoms.

I am now able to corroborate my first statements by additional facts. The latter are based upon a further observation of thirteen cases, in which the *transitory character of certain instances of regular astigmatism* has been fully established.

I shall not be guilty of wearying the audience by a monotonous exposition of all these cases, however interesting they may be. A brief summary of three cases will suffice to illustrate my proposition:

CASE I.—The twelve-year-old boy McE. came under my treatment October 26, 1882, on account of weakness of his eyesight, which had rendered regular work impossible. He has been suffering for several years from violent headaches, with which were lately associated noises in the ears. He had stammered before, but slightly and occasionally only. This disorder has now become permanent for the last few months. There were marked anemia and nervousness; the eyelids were in constant nictitation; the external appearance of the eyes was normal; all the other organs were in good condition.

Vision of the right eye was 12-70; concave 1-12 increased vision to 12-30; concave 1-12, combined with concave cylindrical 1-18, 65°, brought vision almost to 12-20. Vision of the left eye was 12-100; concave 1-20 increased vision to 12-40; concave 1-20, combined with concave cylindrical 1-26, 105°, brought vision to 12-20. There were besides weakness of the internal muscles and marked venous hyperæ-

mia of the retina. The boy was not able to continue reading for a few moments, not even medium large print. He turned the book soon to the right, soon to the left side, raised and lowered it, and seemed to feel easiest by holding it in an oblique position to his visual line, the head turned on the vertical axis to the left. The eyelids, which were in constant nictitation, closed spasmodically on protracted efforts of accommodation, which had besides the effect to call forth lachrymation and congestion of the ocular conjunctiva, with a sensation of intense pain and pressure in the forehead and in the temples. Photophobia was not present, and the eye could stand even strong light with great ease.

I abstained from any internal medication, however tempting it was to try to build up the system by roborantia. My treatment consisted merely in absolute rest of the eyes and in the use of duboisine, by which maximal mydriasis was kept up. With the abatement of the spasm of accommodation, which was marked by a decrease in the degree of myopia and astigmatism, and by an increase in vision, the general health improved, headaches and nervousness subsided, and stammering returned to its former condition.

The final result of the treatment, as noted down January 12, 1883, was as follows: Vision of the right eye 12-15; concave 1-42 increases vision to 12-12. Vision of the left eye 12-15; concave 1-60 increases vision to 12-10. No astigmatism in either eye. The weakest cylindrical glasses at my disposal, concave 1-70, impairs vision. Equilibrium of the muscles perfectly restored. Retina normal.

Examination, repeated June 2d, showed no change in the condition of the eyes, the latter have done their due amount of work without ever causing the slightest annoyance.

CASE 2.—The ten-year-old boy B. came under my treatment October 2, 1878, for progressive myopia and asthenopic trouble, with the following condition of his eyes: Right eye, M. 1-16, V. 15-70; concave 1-16, combined with concave cylindrical 1-36, 95°, increases vision to 15-30. Left eye, M. 1-14, V. 15-40; concave 1-14, combined with concave cylindrical 1-24, 105°, increases vision to 15-20. The parents of the boy are highly myopic, and there is myopia in the respective families.

A three months' treatment by means of heurteloups and atropine had the effect to increase vision to 15-12 in each eye and to remove myopia and astigmatism. In spite of the many hurtful influences to which his eyes were subjected, the latter gave no cause of complaint until the fall of 1882, when symptoms of asthenopic troubles and of irritation developed in conjunction with the reappearance of myopia. Examination, made December 4th, revealed: Right eye, vision 12-50, with concave 1-24, V. 12-30, combined with concave cylindrical 1-36, 90°, V. 12-20. Left eye, V. 12-100, with concave 1-10 respectively 1-9, V. 12-50, combined with concave cylindrical 1-30, 90°, V. 12-20.

A two weeks' use of duboisine and perfect rest of the eyes improved somewhat the condition, but treatment proper had to be deferred until the summer vacation. June 25, 1883, examination showed: Vision of the right eye 12-50, concave 1-18, increases vision to 12-30; concave 1-18, combined with concave cylindrical 1-20, 125°, increases vision to almost 12-15. Vision of the left eye 12-200, concave 1-8, increases vision to 12-50; concave 1-8, combined with concave cylindrical 1-16, 105°, increases vision to 12-20. Weakness of the internal muscles, marked retinal hyperæmia. Region around the macula lutea slightly suffused.

The use of duboisine and heurteloups, and perfect rest of the eyes gradually led to perfect recovery. The final result, noted October 3d, was: Right eye, V. 12-12; it bears concave 1-70, but not concave 1-60. Left eye, V. 12-15, concave 1-45 up to 1-36 increases vision to 12-12. With both eyes (without the use of concave glasses), vision is 12-10. Astigmatism entirely vanished. Equilibrium of muscles restored. Retina normal.

CASE III.—The fourteen-year-old boy W. was brought to me December 27, 1882, on account of asthenopic troubles and weakness of his eyes. Examination showed: Vision of the right eye 12-50; convex 1-70 up to 1-42 increases vision to 12-20. Vision of left eye 12-40; convex 1-60 up to 1-42 increases vision to 12-20. Cylindrical glasses do not improve vision. There is marked spasm of accommodation.

My proposed course of treatment was not agreed to at the time. The boy continued working until March, 1883, when his eyes failed totally. He resorted to another oculist, who ordered him the following glasses for near work: *Concave 1-40, combined with concave cylindrical 1-36, 120°, and prism 2°, base inward for each eye.* They acted at first like a charm, and patient was able to continue his studies for a few weeks, but then the condition changed to the worse. A modification in the glasses—*concave 1-30, combined with concave cylindrical 1-36, 120°, and prism 3°, base inward for each eye*—ordered by the same physician, proved without avail. The slightest effort of accommodation provoked the most agonizing headaches, nausea, and even vomiting; vision became as bad for distant as for near objects; the general health suffered considerably. Patient lost flesh and appetite and became of very irritable temper. In this condition he was intrusted to my care, June 28th, after a treatment for dyspepsia had proved a total failure.

The examination showed: Vision of the right eye 12-70; concave 1-20 increases vision to 12-40; concave 1-20, combined with concave cylindrical 1-20, 105°, gives vision 12-20. Vision of the left eye 12-100; concave 1-18 up to 1-16 increases vision to 12-50; concave 1-18, combined with concave cylindrical 1-30, 110°, gives vision 12-20. Medium small print (Jaeger 8) is read with great effort, the book being kept close to the eyes and askant to the visual line, the head turned on the vertical axis somewhat to the left. The lids are in constant nictitation, with intervening spasmodical contractions. There are marked lachrymation and photophobia. Both retinæ show intense venous congestion.

The same treatment as has been described in the second case gave, October 2d, the following result: Right eye, vision 12-10; left eye, vision almost 12-8. Both eyes bear convex 1-60, but not a higher number. With both eyes (without the use of glasses), vision is 12-8. With the help of convex 1-60, vision reaches almost 12-7. No trace of astigmatism. All disorders vanished. General health good.

Miscellany.

THERAPEUTICAL NOTES.—*Chloral as a Purgative.*—Writing in the "Gazzetta Medica Italiana, Provincie Venete," Dr. Bonatti speaks highly of the use of hydrate of chloral as a purgative in cases of obstinate constipation in insane persons, after jalap, croton-oil, and other drastic cathartics have been used without avail. He gives the chloral in doses of two or three grammes (thirty to forty-five grains), dissolved in a draught of infusion of senna. It is said to act rapidly.

The Quinine Treatment of Whooping-Cough has been made the subject of renewed investigation by M. Poskin ("Annales de la Soc. méd.-chir. de Liège," Aug., 1883), who has compared it with the methods of treatment by the bromides, by belladonna, and by emetics. In twenty-eight cases in which he employed the tannate of quinine he found that it invariably shortened the spasmodic stage, and diminished the intensity of the paroxysms. He does not agree with Binz that its action is that of a parasiticide, nor does he regard it as a specific. He prefers to give large doses toward evening, all within the space of half an hour. For children he uses the tannate, but for adults the sulphate.

Phosphate of Codeine.—The ordinary salts of codeine, the sulphate and the chloride, in spite of the gentleness of their action and the comparative freedom of the patient from disagreeable after-effects from their use, have practically been found inconvenient on account of their difficulty of solution in water. At the suggestion of Professor Hegar, of Freiburg, Merck, of Darmstadt ("Memorial," 5, 1883), has succeeded in making a phosphate which seems to be free from this objection, for it dissolves in four parts of water, the solution containing seventy per cent. of the alkalioid.

ARTIFICIAL OYSTERS are supplied to the Paris markets, according to a *feuilletoniste* of the "Union médicale." They are colored by means of copper, and are cemented to the interior of old shells.

Lectures and Addresses.

A MEMOIR OF

DR. JAMES R. WOOD.*

By FREDERIC S. DENNIS, M. D.

MR. PRESIDENT AND FELLOWS OF THE NEW YORK ACADEMY OF MEDICINE: We have met this evening to consider the work and character of a man to whom American surgery owes much—James Rushmore Wood. It is only a little while since he died, and the impress of his genial, earnest, determined personality is fresh on all our hearts. He was loved, as well as respected and trusted, and, while memory and reason endure, this friendly affection and the sense of personal loss created by his death will continue. It is almost a sacred duty that we are called upon to perform. During Dr. Wood's illness his mind, released from those rigid restraints of reason to which it so readily yielded during his life-time, sought this hall. Again, in his disordered fancy, he was speaking here, as you have so often heard him speak. This honorable and venerable Academy thus stood to him, in the passing delirium of those last hours, as a trusted friend, the old homestead, or a dear child often stands to other men. His mind reverted to it under the pressure of a native and constitutional instinct. He lived in the great profession to which all his powers were devoted, and from which he was taken while still a worker, and to this place and to this platform, as the visible representation of the successful efforts of American medicine and surgery to diminish pain and to prolong life, his dying thoughts fled in touching obedience to original impulse and the need of kindred association. There was perfect fitness in all this. With this society more than with any other he was personally identified. Under the auspices of this Academy Dr. Wood made his most valuable literary contributions to the profession. In this room and upon this platform he made his last public address. It is therefore pre-eminently proper that we should consecrate *here* to his memory, out of our respect and love for him, a perpetual token, which will endure, which is sincere, which is spontaneous, and which, as it reveals his familiar lineaments upon the painted canvas, also shows our innermost thoughts of him.

James Rushmore Wood, M. D., LL. D., was born at Mamaroneck, N. Y., on the 14th day of September, in the year 1813. He was the only child of Elkanah W. Wood and Mary Rushmore, both of whom were Quakers. The father was a miller, and the little family remained at Mamaroneck until the baby was two years old. In 1815 Mr. Wood moved to New York city, establishing himself and family at No. 13 Jacob Street, where he kept a finding and cut-leather store. Later, the family lived on the corner of Frankfort and Pearl Streets, where Mr. Wood opened a drug and herb store. During his boyhood James was very delicate, and on this account it was the family custom for many years to send him for the summer to an aunt's, who lived

at Half Hollow Hills, in the neighborhood of Deer Park, on Long Island. As a lad he was fond of fishing and shooting. Singularly enough, in those early years he spontaneously formed the habit of preparing the skeletons of fishes and birds, and thus collected quite a little museum. His natural inclination for anatomy colored and determined the sports of the boy. Indeed, it is altogether reasonable to say that the sports of the boy determined the vocation of the man. His early and original taste for anatomy without doubt directed his attention toward the study of medicine; and in the rude and trifling museum of his boyhood we can see the germ of that magnificent product and monument of his later years, the Wood Museum of Bellevue Hospital. Dr. Wood never enjoyed a college education. His meager schooling was obtained at the Friends' Seminary, a little institution which was under the direction of the Quaker meeting-house in Pearl Street. In this place he received his early and his only academic education. Upon leaving the Friends' school, he entered, in 1829, upon the study of his chosen profession. It was at this time that his mother died. There is a tradition that his mother had some preferences for the ministry as a vocation for her boy. This often happens in the case of loving mothers of delicate and only sons. But the young man's instinct was *surer* than his mother's wish. He ministered to the soul through the physical environment of the body with a power and a capacity that she never dreamed of, and by a different route, but one upon which he was always at home, he became a "good physician" after all. His preceptor was Dr. David L. Rogers, who was called the "Mott of the eastern side of the town." At that time Dr. Rogers had thirteen students, two of whom are still living—Dr. Murphy, of Mount Vernon, N. Y., and Dr. Whitney, of Norwich, L. I. By a happy chance Dr. Wood met these two student-associates at a railway station a short time before his death, and the three spoke of their survival and the incidents suggested by it.

Dr. Wood attended his first course of medical lectures at the College of Physicians and Surgeons, which was situated at that time in Barclay Street, during the winters of 1830-'31 and 1832-'33. In 1833-'34 he went to Castleton, Vt., where in 1834 he was graduated; and soon afterward he was appointed Demonstrator of Anatomy by the late Dr. Alden March, of Albany. Very soon after his graduation he began the permanent practice of medicine in New York city, his first office being situated in the Bowery near Grand Street, and his partner being a Dr. Sibley, who was a student with him at Castleton. It appears that he had practiced medicine here under a license before being graduated, which was not an unusual thing to do in those early days. Hence his name appears in the city directory as a physician some few years before the date of his graduation. He had not been settled long in this office before the building containing it was burned, involving the destruction of all his books, instruments, and specimens. This was a very serious loss to him, occurring as it did at the outset of his career. This fire led to his removal from the Bowery to 67 East Broadway, and soon afterward to 77 East Broad-

* Read before the New York Academy of Medicine, January 3, 1884.

way, his business at this time already having become large. He lived at 77 East Broadway until 1853, when he was married to Miss Emma Rowe, daughter of Mr. James Rowe, a retired merchant of New York. He then moved from 77 East Broadway to No. 2 Irving Place, where he resided until 1865, when he moved to No. 80 Irving Place, where he was living at the time of his death. At that time his family consisted of Mrs. Wood, one son, Mr. James Rushmore Wood, and two daughters, Miss Ida Wood and Mrs. Bell, wife of Mr. Louis V. Bell, a son of Mr. Isaac Bell, who married a daughter of the late Dr. Valentine Mott. One child died in infancy.

In a brief memoir suitable for the Academy it is impossible to trace Dr. Wood's remarkable professional career step by step. Neither is it necessary. His public honors and his hospital appointments, for example, are well known to this audience. I have, therefore, determined to consider some of the more important features of his professional work, since, by looking at these, we shall be able to arrive at a just estimate of his capacity, and to form some conception of the variety and quality of his labors, and the height to which he attained in performing them.

Dr. Wood was a wise founder in the matter of medical instruction, he was an apt and sympathetic teacher, and he was a great surgeon. What he did in any one of these three lines of effort would have entitled a man to the gratitude of posterity; but, carrying on all three, as he did, with equal ability and success, we may unshrinkingly forestall the instructed judgment of those who are to come after us, and say that Dr. Wood's work, both for quality and utility, will always take an honored rank among the best. In order to understand the vital relations which Dr. Wood sustained toward Bellevue Hospital from the beginning, it is necessary to consider the early conditions out of which that time-honored and renowned institution sprung. Before 1800 the ground upon which Bellevue Hospital now stands was an open park. The place itself was called "Bellevue," on account of the engaging prospect along the river front which the park commanded. There the traffic on the swift-flowing currents of the East River had for a background the soft greens and grays of the open and unused country on the farther shore. This park was surveyed and purchased by the Common Council, which erected the almshouse, and such eleemosynary institutions as now are found on Blackwell's Island. These buildings at that time all stood together in this park. Previous to 1846 Dr. Wood was a great politician; but he was unlike most politicians at that time and since in the particular that he never sought a public office, and could not be persuaded to accept one in any circumstances. His natural political enthusiasm and his indefatigable efforts in the political work of the times brought him into personal relations with the politicians, among whom and with whom he was an influential source of power. For example, his admiration for Henry Clay was unbounded, and they were warm personal friends. Clay used to visit at Dr. Wood's office in East Broadway on the most intimate terms; and among the many valuable souvenirs received from Clay was the cane which Dr. Wood carried on special occasions to

the time of his death. Now, this was the state of affairs in regard to the institutions in the open park, and this was the political relation which Dr. Wood held toward those in power in New York city; and, by the ordinary process of human action and reaction, Dr. Wood was finally instrumental in securing control of these institutions. He saw in the almshouse and the other institutions a vast quantity of clinical material for medical teaching. He endeavored, with others assisting, to get control of this material for the purpose of medical education. He succeeded in inducing the Board of Aldermen to appoint ten governors to manage these institutions. This was brought about, and Drs. Parker, Metcalf, and Wood were appointed as a board of medical men.

Dr. Reese, the resident physician, was dismissed; a warden was appointed; the medical board was enlarged, and the hospital now known as Bellevue began to be managed as it is to-day.

Dr. Wood, from the beginning of his connection with Bellevue Hospital in 1847, began to collect post-mortem material with the intention of founding a museum. As an aid in the accomplishment of this object he offered prizes for the best anatomical dissections; and, after accumulating specimens for nearly twenty years from his private and hospital practice, he presented the collection, in 1856, to the Commissioners of Public Charities and Correction. From the time of its acceptance by them to the day of his death his interest and enthusiasm for it remained unabated. He daily visited the museum, supervised the completion of the catalogue, and personally directed every improvement. It was his ambition to make the museum, which bore his name, as complete and exhaustive as possible in every department. He desired to leave behind him this collection as a monument of his indefatigable zeal and unflagging interest in pathological anatomy. Dr. Willard Parker lately remarked that the "Wood Museum," as it now stands, was the grandest monument ever erected to any surgeon in this country; and the London "Lancet," speaking of its rich collection of unique specimens, said: "It is not a little remarkable that this museum, like our own Hunterian, owes its origin to a distinguished surgeon whose work is known all over the world, including especially some of the most beautiful and successful instances of operation for the reproduction of bone."

Dr. Wood's interest in pathological anatomy did not impair his enthusiasm for clinical medicine and surgery. Having obtained possession of the dead material for the purposes of scientific research and inquiry, the sequence was a logical one to the appropriation of the living material around him for medical teaching. To this end Dr. Wood devoted his energies, and the result was an appropriation of public money by the commissioners for the erection of a building for medical instruction. That edifice was called the pathological building, and is, in part, the main structure of the museum to-day. It was here that Dr. Wood began his first clinics. With the house staff and one person only as an audience at the outset, his clinic grew until at the time of his death the audience oftentimes numbered nearly a thousand. The opening of this building for medical teaching was an important event, foreshadowing the estab-

lishment in 1861 of a chartered school of medicine, which Dr. Wood, with the co-operation of three other medical men, had succeeded in creating, and which has grown steadily in its influence until it has reached its present degree of prosperity.

Dr. Wood was foremost in the view that medicine is a science pre-eminently of demonstration as well as of observation, and it was the union of clinical and didactic teaching that in his opinion best attained the object of medical education. This twofold principle of teaching was an abiding rule of his life; and he always endeavored to demonstrate to others what he had acquired by observation and study. The gradual growth and completion of the system of joint clinical and didactic teaching owe, in great part, their parentage and nurture to Dr. Wood.

As a skillful surgeon and experienced operator Dr. Wood stood in the foremost rank of American surgeons. In dexterity he had no superior in this country. His fame as a beautiful, quick, and sure operator was thoroughly well known throughout the land. Dr. Francis has happily and accurately described his methods as follows: "Dr. Wood is bold, free, confident. Cutting well either with his left or right hand, he performs the most serious operations with becoming skill and with the happiest results. It has not been so much his desire to originate new practices as to improve on old ones, and, by a careful ratiocination, to arrive at important issues." Dr. Wood's great celerity as an operator was of immense advantage to him before anæsthetics were introduced in surgical practice. He has amputated a thigh in nine seconds; and this wonderful rapidity of skilled manipulation often determined in those days the success of an operation. The necessity of operating rapidly has now been done away with through the modern resources for arresting hæmorrhage and annihilating pain.

As a *hospital* surgeon, Dr. Wood has a most enviable reputation. His hospital operations were brilliantly successful. The magnificent results which he obtained were due to the unflagging interest, unflinching energy, and untiring watchfulness which he displayed in the treatment of his hospital cases. No house surgeon ever served under Dr. Wood who did not feel that his success was due to his indefatigable care. The night was never too cold nor too dark, the day never too inclement, his professional engagements never too numerous, to draw him away from his *hospital* duties. He visited Bellevue regularly and irregularly, and frequently many times in the day unexpectedly. By day and by night, month after month, and year after year, Dr. Wood was always at his post; and he loved Bellevue and her interests. Every member of the hospital house staff felt that in Dr. Wood he had a true friend; and he was appealed to by them in every emergency, and always responded in their behalf with the weight of his influence and power. Even the students sought his kindly help, and none ever applied to him in vain. It was this unflinching good feeling on his part toward the students that made him so much beloved and honored by them. His great familiarity with the routine and executive work of Bellevue in every department made him its recognized and official head.

Nothing could be done there which escaped his notice; he was aware of everything, and his name became so identified with the executive management of this renowned hospital that all tacitly, if not openly, conceded to him the authority with which tradition had invested him. From the visiting staff to the house staff, from the executive head to the most insignificant employee of Bellevue, all conceded his right to dictate, his power to interfere, and his influence to control.

Dr. Wood's success as a hospital surgeon was clearly due to his watchfulness after every operation. He scrutinized everything, he watched every symptom, and, by this painstaking espionage, he was on the alert to detect and to combat at once any unfavorable sign. He was clinically precise, and strictly conformed his plan of treatment to well-recognized and thoroughly established rules of surgery. He believed conscientiously that good results were only to be attained by conforming to certain fixed precepts. He was punctilious to a fault in the matter of surgical cleanliness, and never permitted his surgical dressings to have the slightest suspicion of uncleanness. He impressed upon his students and his house staff the one maxim, that surgical cleanliness is the *sine qua non* of surgical success. He was scrupulously particular about the employment of any agents in his dressings which might possibly carry infection. In late years he never used a sponge, not even during an operation, but always pieces of sheet-lint soaked in carbolic acid, and these extemporized sponges were destroyed after the operation.

Rest, cleanliness, and free drainage were the special agents he employed in his treatment of wounds. He considered the smallest detail in dressing a necessary condition to the success of the case. Nothing was too trivial, nothing too insignificant, to escape his eye; and he enforced with rigid exactitude the carrying out of details which to some appeared superfluous. His exactions in the matter of surgical dressings would appear, to one not familiar with his ways, as almost absurd. But no one ever worked in co-operation with Dr. Wood, or under his direction, who did not concede that he was right. He would seem at times to those working under him to be unreasonable in his demands, but, in fact, he was wholly absorbed in the patient's welfare and the advancement of the science of surgery. Every one associated with him, in the capacity of a student or an assistant, came to understand that his military precision and his inflexible determination to have no possible precaution omitted were due to the just importance which he attached to the work in hand; and he rightly judged that, in order to secure the proper attention in important cases, it is necessary to require it in *all* cases. Stern and unyielding upon this professional side, he always carried with him the warm and helpful human side, which those associated with him freely sought, and not in vain. He was singularly acute in his perceptions of the nature of a patient's disease. He had great powers of clinical observation; he possessed wonderful diagnostic faculties; and oftentimes he would detect something which would appear trifling to observers, but which would immediately throw light upon the case.

The literary contributions which Dr. Wood made to

medicine and surgery were not numerous, but the few were of great practical importance.

In 1845 he published an article on Strangulated Hernia in the "New York Medical and Surgical Reporter."

In 1847 he contributed a paper on "Spontaneous Dislocation of the Head of the Femur into the Ischiatic Notch occurring during Morbus Coxarius." Dr. Wood showed in this monograph that these dislocations were very rare, and that they were not really dislocations; but he attributed all the signs of dislocation to organic changes in the form and relations of head, neck, and great trochanter of the femur, as well as of the acetabulum. He had beautiful specimens to illustrate his point, and the only ones in any museum in this country or Europe.

In 1848 he published an essay on medical education, in which he urged a higher standard of study. He argued that this could never be brought about by individual effort, but only through some great and controlling body, like the American Medical Association, which represented the various interests of the entire profession.

In 1856 he wrote a brochure upon the subject of "Ligature of the External Iliac Artery followed by Secondary Hæmorrhage." He pointed out the fact that up to that time there had been only fourteen cases of ligation of the external iliac in which secondary hæmorrhage had occurred, and, of these fourteen, ten had died and four survived, his own case being numbered in the list of recoveries.

In 1856 he wrote a pamphlet upon "Phosphorus Necrosis of the Lower Jaw." In this article he presented his views upon periosteal surgery, upon which he had been working for ten years previous to the date of the publication. The regeneration of the jaw by the periosteum was Dr. Wood's most celebrated achievement in surgery; and occurring, as it did, in the early days of periosteal surgery, it may be justly considered as one of the triumphs of American surgery.

In 1857 Dr. Wood published a little work on the "Early History of Ligation of the Primitive Carotid," and included his own nine cases (up to that date) in the report of forty-eight unpublished cases. In this exceedingly interesting paper he made a careful analysis of previous statements upon the subject of ligature of the carotid, and added certain important facts to our previous knowledge concerning it. He shows in this paper that, while the carotid artery had been tied on two or three occasions for hæmorrhage prior to 1803, these cases were never published until after the operation had become a recognized one in surgery; and that our own countryman, Cogswell, of Hartford, tied the artery with only eighteen days intervening from the time of the European operation, and without any knowledge of its ever having been tied. He shows, also, that, while Sir Astley Cooper, in 1805, first tied the artery for aneurism, the patient died, and that the year 1807 records the first successful ligation of the artery for aneurism by Amos Twitchell, of New Hampshire. He thus established for American surgeons a claim which honors our country, and which, indeed, it possesses through the investigations and writings of Dr. Wood.

In the surgery of the *arteries* Dr. Wood's record is in-

deed brilliant. He has ligated the carotid many times for the cure of aneurism, and in one case the carotid and subclavian of the same side, and he has by this procedure successfully cured an aneurism of the *arteria innominata*. In the early days of his professional life he tied the subclavian artery five times in succession, and in every case cured the aneurism. He has also ligated these arteries many times since, but no definite history is left of these cases. He tied for aneurism the external iliac eight times in succession, and cured the aneurism in each case. One patient died, shortly after the aneurism was cured, from uræmic convulsions. The specimen of the obliterated sac is preserved in the museum. Dr. Wood also tied the femoral many times for other causes than aneurism. He resorted to this operation in malignant disease of the knee joint, of the femur, of the tibia, also for acute inflammations of the knee joint with perforating wounds, and finally twice for elephantiasis. Dr. Wood was among the first to cure aneurism by digital compression, and, in 1848, a few months after Dr. Knight's first case, Dr. Wood reported one of his own. He also cured several cases previous to his death by Esmarch's elastic bandage. His success in the treatment of aneurism by well-recognized and by his own methods is indeed an enduring monument to his name.

In the surgery of the *nerves* he was very successful. Among his best operations in this department may be mentioned the removal of Meckel's ganglion with the superior maxillary division of the trigeminus, which he did four consecutive times for the relief of *tic douloureux*, and with the most gratifying results. Dr. Wood did nearly one fourth of all the cases operated upon in the world previous to 1879, since which time the operation has been repeatedly performed. Dr. Wood assisted Dr. David L. Rogers to perform tenotomy upon the tendo Achillis in 1834, and Dr. Wood was among the first to divide the *masseter* muscles in 1840. He also devised the operation of division of the peroneus muscle in chronic dislocation of the tendon, and, as far as I can ascertain, was the first to devise and to treat acute and chronic inflammations of the knee joint by division of the ham-strings and tendo Achillis, with the view of giving the joint absolute rest.

Dr. Wood was also among the first in America to perform resection of the shoulder and elbow joints. The knee joint he resected frequently, and with brilliant results. He has six beautiful specimens of osseous union of the femur with the tibia after resection. The specimens he was able to obtain in some cases several years after the operation. These specimens are still in the museum.

In the periosteal reproduction of bone, Dr. Wood had an international reputation. His museum contains some of the richest and most valuable specimens to be found anywhere in the world. In 1877 Dr. Wood, in response to an invitation from the president of the German Congress of Surgeons, sent some specimens of reproduced bone to Berlin, to be exhibited along with other specimens collected from all parts of Europe. The regenerated lower jaw awakened great admiration among the German surgeons; and the renowned Langenbeck, in his address, said "that he did not believe a corresponding preparation really existed any-

where," and he presented the specimen with the remark that "there was not another such specimen in the whole of Europe as I now show you." This was, indeed, a fitting tribute from one of Europe's greatest surgeons to the genius of one of America's greatest operators.

The London "Lancet," in referring to this celebrated specimen, said that "Dr. Wood is entitled to the great praise of having been one of the pioneers of peritoneal surgery, and the merit of it consists not only in having been then a new kind of operation, but in the details of the procedure, which had to be thought out for the first time, and which have since become recognized principles."

In *genito-urinary surgery* Dr. Wood was known as a lithotomist. He revived Dupuytren's operation of bilateral section of the prostate, and devised an instrument known as Wood's bisector.

He was among the few American surgeons who performed external perineal urethrotomy prior to the year 1840. He removed on two occasions, over forty years ago, renal calculi from patients by incision, and, although the cases never were published, they antedate many operations of the kind in which surgeons have recently claimed priority.

In *abdominal surgery* Dr. Wood achieved great success. The last time that his voice was heard from this platform was in reply to a paper presented by the lamented Dr. Sims, whose distinguished career is considered here to-night in company with that of his opponent in the debate. The propriety of opening the peritoneal cavity in gun-shot wounds was suggested by Dr. Sims, *apropos* of the Garfield case. Dr. Wood, in reply, presented some very cogent arguments against this procedure, and placed great stress upon the fact that opening the peritoneal cavity for ovariectomy in a patient prepared for the operation was altogether a different procedure from opening the peritoneal cavity in a case of gun-shot wound with the accompanying shock. In ovariectomy the shock comes after the operation; in gun-shot wound of the abdomen, the shock is present before, as well as after, the operation.

In the department of *gynecology* Dr. Wood's name is less familiar. He believed that these operations, where necessary, could be performed better by the gynecologist than by the general operating surgeon. Although he did many operations in abdominal surgery, ovariectomy was never performed by him. Perhaps the reason why he never did an ovariectomy may be divined from an incident which occurred in his student days, and which he related to me a few years before his death. He assisted Dr. David L. Rogers on one occasion to perform this operation. When they arrived at the patient's room, they found her just in the act of pushing a barrel of flour into her room from the hall, and this barrel of flour she had alone, by herself, succeeded in lifting and pushing up to the fourth floor from the pavement below. The patient was immediately operated upon, and in a few hours was dead. This incident, of a woman who was well, and had strength enough to complete such a task, and of her dying in a few hours after an operation which in those days was considered scarcely justifiable, made such a lasting and profound impression upon

Dr. Wood's mind that he resolved then and there that he would never perform ovariectomy; and this resolution, formed by him in the circumstances just narrated, he kept throughout his entire life. It is right, however, to add that he overcame his early prejudices, and became an ardent advocate of the operation in the hands of those who were skilled in its performance. One of the last operations he witnessed was at the Woman's Hospital, and performed by my esteemed colleague, whom this night you will hear on behalf of another whose name is famous in this department of surgery.

One of the most important acts of Dr. Wood's professional life had to do with the Dissecting bill, which he, with Drs. Parker, Payne, and Mason, succeeded in getting passed as a law. They saw that the demands of a higher education called for material for dissection, and that an enlightened regard for humanity justified the step. Finally, after four laborious years, they accomplished the work by embodying, in the form of law, that "all vagrants dying unclaimed, and known by the public authorities to be such, and without friends, are to be given to the institutions in which medicine and surgery are taught."

Dr. Wood's work on behalf of the Bellevue training-school for nurses was the outcome of his great desire to further any measure whose object was to alleviate the suffering of the poor. He was the true and faithful friend of this project in its early struggles; and, in conjunction with Professors Austin Flint and Stephen Smith, was instrumental in establishing the school, and in bringing this system of nursing into Bellevue Hospital. He took an active part in the organization of the school; and, though opposition surrounded it at first, he was its champion; and to him are due in great part the incalculable blessings which result from such a charity. The officers of the training-school applied to him for a solution of the perplexing problems continually arising; the nurses themselves looked to him as their benefactor and friend; and the magnificent bed of violets, in multiplied recognition of his own love for that dainty flower, which he always wore summer and winter, which was presented by them against his burial, and which was placed upon the coffin, silently expressed in the most touching way the affectionate and lasting esteem in which he was held by them.

How, now, shall I sum up this surgeon and founder whom we have been considering? The characteristic qualities of his life, the principal exploits of his professional career, are before you. All of you knew him more or less. It is easy to see that the reputation that Dr. Wood attained—although wider than that in store for many of us—is not of overshadowing dimensions. Sheridan's cavalry ride from Winchester made more stir in the world than the most difficult and brilliant of Dr. Wood's operations in surgery. It is obvious that the surgeon must look for his professional immortality to a small and select class. He must be content to be thought highly of by a chosen, educated few; and, in respect to his most important work, he must be content with the appreciation of his professional brethren. As one of this body, I should say that Dr. Wood has done a good work in the world, and that, both as a man and a sur-

geon, he had fully earned the immortality of professional recollection. In this chamber his memory should never wither. In the constructive work of educational opportunities and methods he set in motion forces which will never grow less, but rather greater. What he lacked when a student he has effectively helped to provide for those who are now seeking the field of medical science. As an instructor, he brought clinical and didactic information together in fruitful union. Tradition will long preserve his unsurpassed skill at the operating-table. His contributions to surgical science are permanent. As to the charm of his manner, and the loving regard in which those held him who knew him best, the circumstances of his burial afford ample testimony.

The rich and the poor gathered together to bid our friend, who had done so much for suffering humanity among both the rich and the poor, the last farewell. What was felt then and now Dr. Gross has happily expressed in a personal letter, from which I am permitted to quote: "I felt personally a warm attachment for Dr. Wood. I loved him for his charming social qualities, his kindness of heart, and the uprightness of his conduct in all the relations of life. In his death I felt that I had lost a kind friend, and that another link in the chain of my life is broken. The whole American medical profession will share my regrets, for Dr. Wood was one of its most beloved members and one of its brightest ornaments."

Dr. Wood passed away in the unabated possession of his powers. His death was an interruption. It came to him in all the wonderful activity of his professional life, but it came, as he always expressed the wish that it should come, while he was still working. As it was, he had got through with an immense volume of work. For almost half a century he had been busily toiling for humanity. In private practice, in the hospital, at his office, he had confronted disease and pain. He met these old enemies with new and original resources. That native and constitutional tendency of his mind which brought him into the profession gave him an insight into the subtlest manifestations of disease. He always did all that he could, and that was much. Such a life is a lesson and an example. Fortified by the high professional achievements of Dr. Wood, this life must leave its impress upon the whole American medical profession. Matthew Arnold, in one of his essays, remarks that Chateaubriand said of Joubert that "a man can live in the world's memory only by what he has done for the world." And so we may say that Dr. Wood deserves a good measure of the world's recollection, because in his work in the matter of medical education and systematic nursing he builded for the future as much as for to-day, and the effects will be lasting, rational, and useful.

THE DUPARQUE PRIZE will be awarded by the *Société de Médecine*, of Paris, in 1885, for the best essay on the pathology of the ovary, and especially oöphoritis. Competing essays, which must be written or printed in French, should be sent to M. le Dr. Thorens, 34 rue de Penitence, Paris, before the 1st of January, 1885, and they must not have been published more than two years before that time. As the prize was not awarded in 1883, it will amount to 1,200 francs, in addition to the gold medal.

Original Communications.

MIGRAINE.*

By C. H. HUGHES, M. D., St. Louis,

LECTURER ON NERVOUS DISEASES, ST. LOUIS MEDICAL COLLEGE.

MIGRAINE, or megrim, is ordinarily the periodical protest of cerebral over-tax in the acutely exhausted, comparatively young, brain of a mildly neurotic subject.

It belongs especially to the time of life—from early puberty to middle manhood—when emotional disturbances—fret and worry—most violently agitate and accompany the intellectual movements, and when the latter are most active and impulsive. It is a temporary disequilibrium between waste and repair in the higher cerebral centers, a comparative neurasthenia from mental over-strain which expresses itself in slightly neurotic subjects, like the outcry of an oppressed or famished nerve in neuralgia. It is not denied that it may be precipitated by other conjoint causes than cerebral over-strain, especially such as contribute to congest the head by exciting disequilibrium in the systemic circulation; but an hereditary tendency to weaken under a certain degree of over-strain on the part of the cerebral vaso-motor system, and the coexistence of that strain, which can not be resisted, constitute the essentials of an attack of migraine.

Migraine usually expresses itself unilaterally, because one hemisphere—and that on the left side, the driving hemisphere, as Ferrier terms it—gives out first, the hemisphere to which the heart's blood goes most directly.

Migraine is periodic (but not equidistantly so), because a certain stage of exhaustion must be reached—longer in some individuals than in others, and longer in the same person at certain times and under certain circumstances than others—before the mental machinery resists further goading and the outraged brain asserts its right to rest.

The migrated cerebrum, in refusing thus to be driven to further work, prescribes its own proper therapeutics—the involuntary rest which the mind is forced to take from accustomed labor and emotional commotion which is worse than labor. The timely recuperation which comes of this repose sooner or later re-establishes the normal equilibrium of recuperation and disintegration, and a reaccumulation of psychical force takes place; a sense of restored mental vigor is again felt by the patient, and eager impulses inspire him to expend it, and he goes along again normally, for a while, expending only the daily accumulations of cerebral force until the more or less nervous temperament of the megrim victim leads, sooner or later, to draught on the reserve nerve force of the cortex and to its final and rapid exhaustion, with a repetition of the previous experience as its sequel. With the lowering of the brain tone from over-tax, the cerebro-spinal dominion over the sympathetic nervous system diminishes; vascular excitations and contractions within the cerebrum, followed by vaso-motor paralysis and dilatations of vessels, and the meningeal pain of distension and pressure and increased, tumultuous, and rapid psychical activity, somewhat like that in the early stage of intoxi-

* Read before the St. Louis Medical Society, January 12, 1884.

cation, follow. Thoughts come thick and fast, till soon the cerebral exhaustion is complete. Sympathetic influences pass downward to the stomach, nausea and emesis frequently follow, and the bowels sometimes move freely. The coexistence of nausea followed by vomiting, and thus by sleep and final relief, has given to megrim the synonym of sick headache; the headache is not dependent upon the sick stomach, but the nausea is due to the sickness in the head. Megrim is indeed a very sick headache, but in another sense. If the vomiting continue long enough, the hemicrania will, of course, cease with the cessation of the vomiting; but, to make the vomiting effective, the stomach should be washed out with lukewarm water till it is empty of all solid contents, and then hot water of at least 115° F. should be given in from four- to six-ounce draughts every hour or two, till about twelve to sixteen ounces are taken. This may be made more acceptable by flavoring with some agreeable tea-leaves or herbs, the commercial tea from China being often acceptable if not made over-strong, and given without cream or sugar. If there should be a loathing for hot drinks along with the usual antipathy to food, then cooling draughts may be given, impregnated with five drops of creasote, or half a drachm of aromatic spirits of ammonia, or carbonic-acid water, or peppermint-water and a little bromide of potassium. The preferences of the stomach, as thus indicated, should be respected.

The hyperæsthetic special sensations all tend to secure that conservation of brain force so essential to the patient's speedy restoration, and their suggestions should be fully heeded in our management of this affection.

Nature, in these sensations, hints strongly at the rational restorative therapy, and such hints to the wise physician should be sufficient. Every movement increases the bodily discomfort, hence the patient asks to be let alone—to be undisturbed.

The hot, aching eyeballs and hot, painful head suggest evaporating lotions, the best of which are the ethereal for the head, and laudanum-and-water, of proper temperature to evaporate readily, for the eyes, for ether is painful if it gets between the lids. The sensitive retinae and troubled vision demand the exclusion of light; the morbidly impressible centers of audition make sounds painful and, in aggravated cases, unbearable. The salivary secretion is sometimes increased, more often altered and disagreeable. To heed nature's demands in these regards is to give the brain, as well as the sensitive centers and channels of audition and vision, the much-needed repose that leads to restoration of exhausted power which has tracked the parts it has forsaken with marks of irritability. The general listlessness and brain-weary feeling which the patient reveals as the painful feelings pass away (if the usual tendency to sleep then does not come on or is interfered with) demand further brain rest, and our therapy and surroundings for the patient should promote rest until an apparently complete restoration follows each attack.

The intervals of freedom from nervous headache should be prolonged by a course of tranquilizing neurotherapy calculated to promote and maintain the nerve stability and

by a moral prophylaxis. To this end the patient should be made well acquainted with the nature of his trouble and the essentials to avert its recurrence.

He should have a mild, unirritating course of constant cephalic galvanization in the interval, repeated daily or every other day, until he has passed the time of several attacks exempt from them. A full dose of ammonium or potassium bromide, 30 to 40 grains, and a minimum dose of arsenious acid, should likewise be given nightly, for many months, in many cases, and as often as three or four times a day for several days preceding the time of an expected attack. Bromide of potassium in forty-grain doses three times a day is of especial service, if the patient is brought fully under its influence when the first orbital disturbances appear, as they do in many of these cases. Guarana may be used to advantage at this time, and subsequently during the attack, but it has not given me the happy results others have ascribed to it. The digestive and assimilative processes are never to be lost sight of, nor any other physical condition calculated in any manner to embarrass the mental movements—to directly or reflexly irritate the brain or to compromise its normal daily nutrition and nightly rest. Beseating sins and moral and physical vices that tend to organic or nervous exhaustion should be inquired into and remedied by discontinuance.

During the attack of migraine the bromides, if the stomach can be made to retain them, are always serviceable, and I give them in large quantities of peppermint-water and minimum quantities of creasote.

In the constitutional treatment of migraine, plenty of pure fresh air and sunlight and a nutritious and digested or digestible and easily assimilated dietary are the best tonics. Spinal and epigastric sinapisms are also of value, and anodyne rubefacient liniments, as of chloroform or camphor and the volatile liniment, with turpentine, capsicum, and oil of peppermint.

A predisposition to attacks of migraine is sometimes awakened by anæmic, cachæmic, or toxæmic states of blood, which especially interfere with normal nerve nutrition in the neurotically inclined. In the first state of the blood the hæmic reconstructives should be mostly ferruginous; in the second ferruginous and specific; in the latter mainly specific, conjoined with good food easily appropriated by the system, which is indicated in all impoverishment of blood. Quinine and arsenic in malarious districts, whether the patient have the usual visible malarial symptoms or not; mercury and potassic iodide in syphilitic migraines (such subjects do have migraine as well as the specific, constant cephalalgia); iodide of potassium and iodine in the migraine of lead-workers; iodine and iron for the scrofulous. Strychnine, arsenic, and cod-liver oil are seldom contraindicated in the anæmic, though the stomachs of many patients revolt at the oil, and it had better not be urged on them. Many subjects of migraine, however, are not anæmic, and some are actually habitually hyperæmic, so far as the head circulation is concerned, and their life habits are such as to keep up an exalted cerebral blood pressure; and, though migraine is to such the most fortunate circumstance that could happen them in putting periodical stops to their over-work and excessive worry, and enforcing resting spells at times in their

over-active careers, they often finally die of grave cerebral affections after they have reached the period when excessive keenness of sensibility, emotional and sensory, ceases. But migraines, like constitutional neurasthenics, are often also long-lived, and not especially liable to grave cerebral disease.

The mistake that has been made in the medical conception and consequent management of migraine consists in its having been regarded as a *want* rather than as an *over-draught* of cerebral power and consequent abrupt collapse in those who, fortunately, are prone to this collapse from exhaustion, short of destructive cerebral lesion. These patients become cerebrastrhenic before brain structure gives way, while others not so hereditarily inclined go on till stopped by apoplexy or aphasia. Subjects of migraine are usually among the milder class of the neurotically endowed, and they do not often have, or congenitally entail, the graver neuroses.

In consequence of this mistake, a coercive tonic plan, so called, but often more stimulating than tonic, has been thought generally the best, whereas the majority of migraines require repression and regulation of their nervous forces; the maintenance, by corrective restraint medication, of a judicious equilibrium in their mental movements, so as to balance daily the cerebral waste and repair. They need to be taught and medicated so as to stand life's frictions, so as to give their brain a reasonable chance for rest and repair, their stomach a fair opportunity to do its work and answer the encephalon's prayer for daily sustenance. They need a physician to constantly advise and regulate them, as they need an attorney in their business affairs to keep them safe from financial shipwreck in many of their ventures.

The business maxims, "never to postpone for to-morrow what ought to be done to-day," and "never to wait for the next train if, by any possibility, the train that has gone can be caught," should be modified to read, "what *ought* to be done to-day, only without violence to your organism, should be done"; and if to-day's train can not be made without over-strain to the system, which may be the beginning of a subsequent breakdown of the cerebro-spinal system, wait for the next train and save yourself.

Migraines, in their best physiological condition, are mentally active, and prone to over-work under business stress. They are ambitious and restlessly inclined to constant endeavor, and seek occupations that readily lead to final over-strain, for when they are busiest they are always happiest.

The rational indications for preventing recurrences of attacks of migraine are repressive cerebral restraints and reconstructive medication. To this end the occupation of the patient should be regulated by his physician, and not alone the consequences of injudicious over-work treated. The nervous system should be tranquilized and the nerve-capital and brain-force economized during the longer or shorter interval between the attacks.

The patient's brain-power should never be squandered. The victim of migraine can not afford to be prodigal of his mental power; if he does, the end of his prodigality will be husks, and he will sooner or later realize that he has unpardonably sinned against nature. It will be fortunate for

him if, in his repentance, he seeks and finds a physician who, instead of goading by a stimulating treatment, represses, conserves and regulates his powers.

Migraine, with melancholic complication some time preceding or following the attack, justifies opium and aloes, or codeine and aloin; but in the habitual management of frequently recurring attacks it is a most pernicious practice to use opium freely enough to subdue the pain, and the same is true of the free use of whisky. Nature needs healthy rest, normal restorative tranquillization, and prolonged, healthy, refreshing sleep; not the enforced and fitful, dreamy somnolency or profound stupor of narcotics. If sleep does not come in due season with the administration of bromide of potassium or ammonium, chloral may be given in a thirty- or forty-grain dose, largely diluted, when the night-time comes on, or when the vomiting and nausea have about ceased. The bromides are good remedies for the precursory restlessness and fidgets; so also the tranquilizing warm bath, if that be at the time convenient to the patient, so that he will not be too much disturbed in being put into it. Valerian-root added to the bath is of value in the hysterical. Under this treatment the tingling sensations and temporary numbness disappear. Hot pediluvia, bottles, and sinapisms to the feet, also to the spine or stomach, are serviceable in arresting temporary vital prostration. The baths and the bromides serve also to tranquilize the heart and relieve the head by diverting the blood from them to the feet, for while the carotids are full the radials are small, and the peroneals and tibials are smaller. I have known the hemianopsia, which is a subjective phenomenon, due to encephalic sanguineous pressure, to disappear during the bath and to be averted by the bromide treatment preceding the coming on of the attacks, likewise the photopsia and photophobia.

Contrary to the statements of Latham and others, that bromide of potassium is more serviceable during the attacks than in the interim, I affirm that, if properly employed, so as to secure a restful state of the nervous system and a tendency on the part of the cerebrum, when not actively employed, to seek repose, its effect is decidedly beneficial in prolonging the intervals and shortening the attacks, and, finally, in preventing the recurrence of the latter altogether. To accomplish this end, the bromide must not be given to sanguineous saturation; and, to be enabled to rely on the smallest quantities of this salt, galvanism must be conjointly employed, and with persistent regularity, if bromism is shown either in eruption, or impaired motility, or cerebral stupidity.

The temporary cerebral hyperæmia of migraine is induced by defective vaso-motor innervation and consequent paralysis of control over the caliber of the cerebral vessels, which are thus allowed to produce a painful degree of cerebral distension.

The turgid brain even robs the face of blood, and the pupil contracts, not only because the retina is hyperæsthetic, but because of irritation of the ophthalmic ganglion and the origin of the third nerve in the gray nucleus in the floor of the Sylvian aqueduct.

It is astonishing how descending cephalic galvanization,

or galvanization over the cervical sympathetic center and under the ramus, and through the head, from the os frontis over the eye to the occipital spine, will cause these symptoms to disappear by the restoration of tone to the vaso-motor system within the head; but, to make the relief permanent, sleep must follow, and rest absolute to the brain as tired nature demands, until recuperation from the exhausting causes that precipitated the attack comes in the course of nature's benignant *vis medicatrix*, assisted by our art. These conclusions are not conjectural, but based upon a success in the management of migraine that has not disappointed, and have been satisfactorily verified in the writer's own person also.

The view of Wilks and others respecting the eradication of migraine is too discouraging and unjustifiably hopeless, due to neglect of suitable management in the interim of the attacks, just as frequently recurring hysterias are thus too much and too often neglected. One of my patients, formerly (eighteen years ago) a two-days victim to migraine prostration every fortnight, now and for fifteen years past has only occasionally (once or twice a year) a reminder in the return of the boring sensation over the eye or on the temple, which a prompt electrization and a drachm of bromide of potassium in peppermint-water cause to disappear. The rest of the treatment he has learned himself: it is to cease going so fast with his work for the time, and take more rest for a few days, and not to fret because he can not accomplish the work of two days in one.

I have encountered a form of migraine that sustains a relation to ordinary migraine, or migraine major, similar to that which *petit mal* bears to the *grand mal*, or epilepsy gravior, and it might justly be termed *hemicranii minor* or *minor*. It sometimes follows, like epileptoid, the graver malady, and sustains the degree of relationship that the simple vertiginous seizures due to the convulsive attacks, or, like the epileptiform disease, it may precede the *haut mal* of megrim.

The case just referred to is an illustration; a patient now under observation had for eighteen months periodic attacks of photophobia, slight photopsia and confusion of vision, cold feet, increased heat, and sense of fullness and slight pain in head, associated with general uneasiness and indisposition to exertion, lasting for several hours of a day in each month, sometimes oftener, if she used the sewing-machine to excess in making her own clothing, always a source of worry to her. The attacks no longer recur since the adoption of the treatment indicated for graver cases—the more moderate use of the sewing-machine and the relegation of her best dress-making to other hands. The making of a stylish dress is sometimes a great strain on a woman's mind. Migraine being self-limited in the duration of its attacks, as it is in its final recurrences, passing away with advanced age, if it does not develop into a graver malady, much of its former therapeutics has been misleading because the attacks have passed off pending the administration of certain drugs, which at best have been of secondary value. Such are valerian, camphor, hyoseyamus, asafoetida, Hoffman's anodyne, ether, etc. An attack may, however, be cut short with chloroform and camphor, or, preferably, chloral

and bromide of potassium, but the sleep which follows should be a prolonged one, and the patient should awake refreshed and in condition to receive, and must have, adequate nutriment to compensate for his exhaustive experience. If he does not, another attack will be likely to recur soon, unless the foregoing hints as to intermediate treatment are put into practice, and this the patient will not always acquiesce in; but migraine, in the intervals of the attacks, should be managed very much like the successful treatment of epilepsy. While relief during the attacks is desirable, it is all-important to the well-being of the patient to prevent their recurrence by intercurrent management.

Addendum.—The extemporaneous character of this paper precludes a full discussion of the asserted alliance between migraine and epilepsy; but there has been demonstrated no real pathological kinship between these two maladies of the nervous system, and the asserted connection between them can not be shown clinically, unless in exceptional instances. True migraine victims comparatively seldom become epileptics in later life, and the coming on of an attack of epilepsy or epileptoid and migraine are essentially different, the one being sudden, with momentary loss of consciousness, often with an aura, frequently in the night, but more often just on awaking from sleep in the morning, and often followed by headache; the other approaching gradually, never with loss of consciousness, generally preceding sleep, or passing away with it, or relieved by it, and never coming on after a profound sleep, as epilepsy so often does.

The general therapy of the two being quite similar proves nothing except that neurotic tranquillization and the balancing and conservation of force are equally valuable therapeutic procedures in each of these neuroses, and that tonicity imparted to the cerebral vaso-motor system, as by the minimum doses of nitro-glycerin, mild cephalic descending galvanism, etc., is equally efficient in warding off the tendency to recurring exhaustion, which in migraine appears to be in the cerebral vaso-motor system, while in epilepsy it appears to be primarily in the psychological or psycho-motor area of the brain, with secondary and rapidly following vaso-motor paralysis.

The hyperæsthesia of migraine and the anæsthesia of an attack of epilepsy are as opposite as consciousness in the one and the absence of it in the other. Headache is the sign essential of the one, while it is the sequel rather of the other.

The occasional beneficial effects of volatile inhalants and stimulants internally in the beginning of each, to postpone an attack, are due to their prolonging nerve tonicity, and preventing the vascular intracranial movement upon which the diverse phenomena of the two different morbid conditions depend. To abort epilepsy, nitrite of amyl, camphor, and the pungent ammonium salts must be inhaled in the very beginning of the aural stage; they are more or less serviceable at any time during an attack of migraine, except the amyl nitrite, the latter, which is the inhalant *par excellence* in epilepsy, often aggravating an established sick headache.

An epileptic subjected to the cerebral-vascular condition of migraine—the arteriole spasm and relaxation—would

always have epilepsy. There is an additional factor in epilepsias which is absent in the brains of migraines, viz.: a tendency to further morbid movement, reaching to unconsciousness and convulsion, founded in the organic constitution of the cerebral texture. Neither of these conditions belongs essentially to migraine, though, when the epileptic diathesis coexists with recurring migraine, the transition is easy and natural into confirmed epilepsy.

OSTEOPLASTIC RESECTION OF THE UPPER JAW FOR PROSOPALGIA; WITH THREE CASES.*

By ARPAD G. GERSTER, M.D.,
SURGEON TO MT. SINAI AND THE GERMAN HOSPITALS.

TOTAL extirpation of the upper jaw as a preliminary measure for facilitating the removal of massive nasal polypi was first successfully done by Syme in 1832 ("Ninth Report of the Edinburgh Surgical Clinic"), and, having been adopted by the then reigning French school of surgeons, remained the standard measure in the operative treatment of the above-mentioned disorder. The happy idea of a more conservative procedure was first conceived and successfully executed by B. v. Langenbeck, in the year 1859 ("Deutsche Klinik," 1859, p. 471), when he extirpated a large retro-nasal polypus through an aperture made by what he designated an osteoplastic resection of the nasal process of the superior maxillary and the os nasi. The ease afforded in the removal of the polypus by this step and the primary healing-in of the resected parts led to further trials, and in 1861 another, more extensive, and also successful case, was reported by v. Langenbeck in the "Deutsche Klinik" (1861, p. 281). This case consisted in the temporary removal of the superior portion of the upper jaw, without injuring the hard palate, the alveolar process, or the velum palati, followed by the excision of a large fibroid of the pterygo-palatine fossa. The steps of the operation were as follows: A curved incision, its convexity looking downward, commenced in the nostril, and extended outward and upward to the middle of the malar bone, the periosteum being divided at one stroke. The masseter was cut away from the edge of the zygomatic arch and the buccal fascia was opened. The lower jaw was now drawn aside, and, the tip of a key-hole saw being introduced into the pterygo-palatine fossa, the upper jaw was sawn through longitudinally above the alveolar process, the cut through the bone following the line of the cutaneous incision to the nostril. A second incision, commencing at the nasal process of the frontal bone, was carried outward along the lower margin of the orbit to join the first incision at the middle of the malar bone. Now the orbit was entered and the eyeball pushed up; then the frontal process of the malar and the zygomatic process of the temporal were divided; finally the orbital plate of the superior maxillary was severed transversely as far as its junction with the lachrymal bone. The resected jaw re-

mained attached by skin and periosteum only to the nasal bone and the nasal process of the frontal bone, and could be easily pried out of its bed by the aid of an elevator, the above-mentioned uninjured parts serving as a sort of hinge. The tumor was readily removed; the profuse hæmorrhage ceased spontaneously, only one ligature, that of the sphenopalatine artery, being required. The resected parts were now replaced, some difficulty being met with in overcoming their tendency to protrude. Wire sutures and a compressory bandage finally effected this end. The cutaneous incision healed almost entirely by adhesion; the bone was found to be immovable on the eighteenth day after the operation.

The value of this truly conservative idea was soon recognized. The operation became well established, and was quite often executed by various surgeons in Germany.

The first one to widen the field of this procedure was Nussbaum, of Munich, who, in 1863, had to deal with an obstinate case of infra-orbital neuralgia of traumatic origin (A. F. Bratsch, "Bayer. Intelligenzblatt," 1863, p. 46, Case No. 13) in a woman of thirty-eight years. Numerous neurotomes of both the supra- and infra-orbital nerves had been performed during the five years preceding her admission to Nussbaum's clinic. In the course of the subsequent two years the cicatrices were repeatedly excised without improvement. Finally, the common carotid was deligated; the ascending ramus of the lower maxilla was trephined in order to permit the excision of portions of the inferior alveolar, the mental, the mylo-hyoid, and the lingual nerves. This led to necrosis and removal of the ascending ramus, but produced a pause lasting five months, after which a relapse occurred, for which v. Langenbeck's osteoplastic operation was performed with temporary success, the observation not extending over more than a few months.

The adaptation of this operation to neurectomy did not attract any attention, at least found no imitators. Billroth, then of Zurich, having excised, in April, 1864, a piece of the infra-orbital, one inch and a quarter long, in what he designated "the ordinary manner," by which Malgaigne's method is meant, and the patient's sufferings not being alleviated, conceived the idea of excising the nerve in question, from the foramen rotundum forward, by the aid of v. Langenbeck's osteoplastic operation.

He believed himself to be the first one who had thought of this plan, but, upon studying up the history of neurectomy, he found that Carnochan, of New York, had preceded him in carrying into effect a similar plan, and also Nussbaum, in executing the identical procedure which Billroth had thought of. Griesinger, who felt a personal interest in the patient, was deterred by the operation, and merely advised the removal of some sensitive portions of the corresponding alveolar process, which was done, accordingly, in May, 1864. The operation was followed by a quiescence of the attacks extending over ten months. The affection reappeared then, and, in February, 1866, Billroth's original plan, osteoplastic excision of the superior maxilla, was successfully performed, and the nerve was cut away close to the foramen rotundum. The operation could be done in an exact manner without serious hæmorrhage. The wound healed kind-

* Read before the New York Surgical Society, December 11, 1883.

ly. The exsected nerve was found to be fully regenerated, and in every respect normal. Meckel's ganglion was not removed. In the ensuing months of April and May, branches of the third division of the fifth pair became the seat of neuralgia, and required sections of the buccinator and mentalis nerve. In July, 1867, the common carotid was ligated with temporary benefit, this lasting till January, 1868, when another relapse drove the patient into Niemeyer's clinic, at Tübingen, where the constant current again relieved him. Here the history stops.

From Billroth's case up to my three operations, no mention of the method as adapted to neurectomy is found in literature.

The late Professor Wagner, of Königsberg, in Prussia, devised the simplest method, and the one requiring the least cutting, by which the foramen rotundum can be exposed. He opened the orbit and laid bare its floor, then pried off the lamina of bone serving as a roof to the infra-orbital canal; then, by a suitable hook, he raised the nerve out of its bed from alongside the uninjured artery, and, following it up toward the round foramen, cut away successively all its branches, and finally the trunk. The integrity of the antrum was thus preserved, yet phlegmon and erysipelas set in in almost all of Wagner's cases. This circumstance puzzled him a good deal, and he attributed it to neuro-paralytic influences. That the operation is difficult and unusually delicate, on account of the confined space, is evident. In cases of a narrow and deep orbit, or where the artery was unfortunately injured, it became almost impracticable, as one of Wagner's own cases (No. 10), König's case, and a third case demonstrated, which I had an opportunity to witness here in 1878. It must be conceded, however, that Wagner's final results as regards the tardiness of the relapses were very good.

The second method to be considered is that devised by Carnochan, of New York. It has its merits, but it labors under the disadvantage of also affording insufficient space, in cases where the facial bones are small, for a sure removal of the entire nerve. Aside from the circumstance that a portion of the superior maxilla must be sacrificed in this method, it is undeniably excellent in suitable cases, and, where a large trephine can be employed, it gives plenty of space and light.

As the third mode of procedure I have to mention Bruns's plan of resecting the malar bone, dividing the muscles presiding over mastication, and thus approaching the nerve from the temple. It is in many ways unsatisfactory, mutilating like Carnochan's operation, the wound is narrow and deep, and manipulation of the nerve is very difficult. Yet a respectable number of patients have been operated on in this manner with fair success.

As an important modification of Bruns's method, Luecke's procedure has to be mentioned, in which the malar bone is not sacrificed, but only temporarily exsected and turned aside, thus giving the operator access to the temporal and pterygo-palatine fossæ. Especially in the presence of a deep layer of adipose tissue and of large masticators, the wound must be very inaccessible.

As the fourth and last procedure we have to mention

preliminary osteoplastic resection followed by removal of the entire nerve. None of the preceding methods can compare with this as regards the space and light it affords, and

FIG. 1.—THE CUTANEOUS INCISION.

the ease with which the infra-orbital nerve can be removed in its entirety. It sacrifices no part of the superior maxilla, and, as statistics prove, is not more dangerous than any one of the preceding methods. With a few modifications, it deserves to be employed in cases not suited for Wagner's method, and merits further trial and development as applied

FIG. 2.—SECTIONS WITH THE KEY-HOLE SAW.

to the alleviation of the terrible sufferings of prosopalgia. Advisedly I do not use the word "cure," since love of truth compels me to admit that our ability to cure prosopalgia is just as uncertain as the knowledge of its pathology is unsettled and unsatisfactory.

The cases observed by me are the following :

CASE I.—Peter Deucker, aged thirty-six. His trade, that of an oven-builder, necessitates his frequently entering bakers' ovens for making repairs. On emerging from a very hot oven he is liable to be exposed to sudden changes of temperature. He said that he had been suffering off and on for eighteen years. In 1877 neurotomy in front of the right supra-orbital foramen was performed by a surgeon with temporary benefit. Large doses of quinine and salicylic acid also modified the attacks to the degree that they become shorter and less severe. In 1878 a re-

mission of three months was brought about by a number of subcutaneous injections of one ninety-sixth of a grain of aconitine, repeated every two hours. At the end of this period mild attacks commenced again, first at long intervals, afterward more frequently; the hypodermic use of morphine was resorted to until the patient had become a confirmed morphine-eater. The attacks had become more frequent and more severe, in spite of the anodyne, and his family attendant directed him to the Mt. Sinai Hospital, where he was admitted May 10, 1881. I found on a well-built frame a somewhat flabby skin and muscular system, the internal organs normal, the patient anxiously avoiding motions of the jaws. On the slightest provocation, such as articulation, chewing, swallowing liquids, or touching any portion of the cheek or lips, the patient's face became distorted and cyanotic, his left eye blood-shot with a copious flow of tears, and, while his hands were pressed nervously to the anterior surface of the upper jaw, his body was bent low down, and a number of deep moans escaped from his chest. The attacks lasted from thirty seconds to two minutes. There were two painful spots—one exactly over the left foramen infra-orbitale, another at the naso-labial junction. The teeth of the upper jaw were the seat of severe irradiating pain during the attack; the lower jaw and tongue were also somewhat affected in this way; the palate was free.

Immediately on admission, a treatment by the constant galvanic current was instituted, but did not produce any notable effect. Hence, after forty-eight hours' preparation, an excision was resolved upon, the anamnestic signs pointing to a neurosis of a peripheral origin, the presumable seat of the affection being in front of the superior alveolar branch of the nerve-trunk.

In selecting the method by which this end should be accomplished, the difficulties encountered in a case of Wagner's operation, witnessed by me, were very vividly remembered. Flooding of the field by blood, soiling of the speculum, hence want of light and space, and especially the impossibility of actually following up and exposing to view the central end of the nerve situated between the foramen rotundum and the infra-orbital canal, led me to abandon this method.

The objections to Bruns's and Luecke's procedures were also great. The powerful masticators of the patient promised to give a good deal of trouble, calling for a very deep wound, the possibility of injuring the internal maxillary artery in which, and the ensuing difficulty of dividing the nerve with any amount of certainty, caused me to abandon these methods also. Compared with Carnochan's operation, the temporary resection had the advantage of not mutilating, of giving decidedly more space, and hence more certainty of accomplishing the chief end of the operation, that is, certain removal of the longest possible piece of the nerve.

The circumstance that the method had not been much tried as an aid to neurotomy was rather an incentive than anything else to a new trial, and to a widening of our experience in the treatment of such an intractable disease as prosopalgia.

Accordingly, on May 12, 1881, the operation was performed strictly after v. Langenbeck, so far as the incisions were concerned, except one modification.

In studying the bearings of the operation on the object in view, I found that the section through the frontal and temporal processes of the malar bone could be advantageously replaced by a simple division of the middle of the malar bone. The injury would be lessened, and yet enough space would be afforded for attacking the nerve. In addition to this, the supra-orbital foramen being exposed, the nerve was divided about two eighths of an inch in front of it. In sawing through the superior maxillary the hæmorrhage was considerable, especially when the

nasal mucous membrane was severed, but never alarming, and it ceased spontaneously. No difficulty was encountered in turning the resected block out of its niche, and the nerve was seen to slip easily out of the infra-orbital canal, and was lying at full length on the bottom of the wound. The alveolar and dental branches had been necessarily torn off. The trunk of the internal maxillary could be seen pulsating in the posterior part of the wound, covered by the periosteum stripped off the tuberosity of the maxilla. To expose the foramen rotundum fully, some remaining portions of the orbital plate of the maxillary bone had to be removed by forceps; then the nerve was grasped and easily cut off close to the foramen. No ligation was required. The parts, having been thoroughly mopped with an eight-per-cent. solution of chloride of zinc, were easily replaced, and the cutaneous wound was closed with catgut sutures. A small drainage-tube was passed into the speno-palatine fossa, leading out beneath the zygoma. No dressings were applied. The anesthesia, by chloroform, was never full except while the first incisions were made, and the blood entering the fauces and larynx was readily expectorated. The length of the excised nerve was one inch and seven eighths; the time consumed, one hour.

On recovery from the anesthesia, the patient at once touched his cheek, and was delighted at the absence of pain. Anesthesia of the corresponding parts was present; the return of sensation was ascertained on the fifth day about the ala nasi, on the twelfth over the foramen. Bloody serum oozed out of the tube for about a week, then gradually the discharge became seropurulent and scanty, so that the tube was removed by the end of the second week. No fever and no local reaction followed, and the cutaneous wound healed by adhesion. The resected part had become immovable in the fourth week. The neuralgic attacks had ceased immediately after the operation, and the patient was discharged from the hospital to resume his occupation. In the winter of 1882-'83 slight attacks commenced to manifest themselves again about once a week, the point of the most intense pain being the upper lip near the ala nasi, and the irradiation to the teeth of both upper and lower jaws of the right side more marked than ever before.

I directed the patient to a distinguished neurologist for treatment in May, 1883, but, both medicinal and galvanic therapy proving quite futile, and the attacks gaining in violence, the patient implored me to relieve him by an operation. It seemed pretty certain that extensive regeneration of the nerve must have taken place, and that its dissection from the cicatrix in which it must necessarily be imbedded promised to be a difficult task. Weighing all the circumstances, Carnochan's procedure seemed to promise most success, enabling me to expose the entire length of the infra-orbital canal and Meckel's ganglion. Being readmitted, the patient was put under the influence of chloroform on June 16th, and, a crucial incision exposing the foramen infra-orbitale, a number of thread-like nerves were found to radiate from it. The antrum being opened by the aid of the trephine, the infra-orbital canal was exposed, and a slender, irregular-shaped cord of varying diameter could be dissected out of it. The posterior wall of the antrum was broken out with a fine chisel, and Meckel's ganglion, together with the internal end of the nerve, was removed with forceps and scissors. The excised cord proved to be composed of nerve-tissue. To make sure of the destruction of the nerve as far as possible, the blunt point of a thermo-cautery was inserted into the foramen rotundum, and the parts were thoroughly seared. The patient, on recovering from the anesthesia, complained of violent, constant pain in the jaw, although the skin was found to be quite anæsthetic. In spite of a free use of hypodermic morphine injections, he spent a wretched night, the

attacks being now more frequent and violent than ever, the intervals between them never exceeding five minutes.

This gloomy aspect of the case continued until the discharge from the wound, which was lightly filled with iodoform gauze, commenced to be unmistakably purulent, which took place on June 19th. The highest temperature, 100.5 F., was recorded at this date, and the night was spent tolerably well with two injections of morphine. The two nights following the 19th were spent comfortably with the aid of one injection of morphine. On the morning of the 21st several sharp attacks were noted. Two more attacks came on the evening of June 22d, requiring an injection. The day and night of the 23d were spent painlessly and very comfortably, no morphine being required. The discharge from the deep parts of the wound was purulent and copious, but the skin was never inflamed. From this time on the case did well, the attacks not returning. By July 16th there remained only a fistula, into which a probe could still be passed to a distance of two inches and an eighth. Very slight fornication, with tenderness, appears once in a while in the course of the second branch; and lately the patient has had some pain in the course of the third branch.

CASE II.—Catharine Diemer, widow, aged forty-two, admitted to the German Hospital, January 2, 1882. She stated that she had suffered from paroxysms of intense pain in the upper lip and the right alveolar process for two years preceding, no cause for the same being known to her. She had had all the teeth of the right upper jaw extracted one after the other, although they were sound. All this had had no influence on her sufferings. The pain irradiated into the ear. She never had had otorrhœa. She had been under treatment for three months in the German Dispensary for a circumscribed necrosis of the alveolar process of the second molar, undoubtedly due to the last tooth extraction. The sequestrum was removed when loose, and a fistula leading into the normal antrum was found. The alveolar process had become much atrophied, and was seen to be invested by normal mucous membrane. Dr. Gruening kindly consented to examine her ear on January 6th, and found a normal drum, no perforation, acuteness of hearing slightly diminished, pointing to a chronic otitis media, the Eustachian tube free. The necessary instrumental manipulations did not produce any attack. Probing of the antrum by the fistula, touching of the alveolar process, and chewing always caused acute pain, which, however, was apt to occur spontaneously, too, especially at night.

All other resources being exhausted, a neurectomy was decided upon, and was carried out in the German Hospital on January 19th, almost in the same manner as in the first case. Profound ether anæsthesia was maintained only while the cutaneous incisions were made. Owing to their slight proportions, the sections through the facial bones were easy and rapid. The hæmorrhage was at first somewhat copious, but ceased spontaneously. In the light of the experience gathered in my first case, the division of the orbital plate of the superior maxillary was so modified as to run in the antero-posterior line from a point of the infra-orbital margin midway between the lachrymal duct and the infra-orbital canal, backward and parallel with this canal, to the inferior orbital fissure. Thus injury to the nerve and the lachrymal duct was avoided, and the slight tuberosity marking the inner side of the posterior end of the infra-orbital canal, the chief obstacle to a free exposure of the sphenomaxillary fossa, was got out of the way. On turning out the resected mass, the nerve was seen to slip easily out of the canal, and could be readily followed to and cut away at the foramen rotundum, the portion removed measuring an inch and three fourths. The hæmorrhage was controlled throughout by slight compression. The wound was closed by catgut sutures, and capillary drainage of the sphenomaxillary fossa by a few

strands of catgut was employed. The cutaneous incision healed throughout by adhesion; the place where the catgut drain lay continued to discharge a slight amount of serum for two weeks, then closed. Anæsthesia was fully established immediately after the operation, but the time of the return of sensibility was not noted. The attacks had ceased, and did not return till March, 1883, when she again complained of pain in the upper lip, the attacks being of a mild character and of short duration, and easily controlled by small doses of morphine.

CASE III.—Jacob Kahn, drygoods clerk, aged sixty-three, a well-built and well-preserved man, who was unable to name a cause for his complaint. The first series of severe attacks of facial pain occurred in November, 1879, and lasted for four weeks. Its seat was at the point of exit of the left infra-orbital nerve on the face, the pain irradiating into the upper teeth, the lower eyelid, and the left ala nasi. It was subdued by local injections of morphine, and a pause of three months followed. Since the spring of 1880 the paroxysms had become somewhat more frequent, were most easily produced by mastication, but were controlled by morphine. In the spring of 1882 the attacks grew more severe, and the patient sought relief in an institute established for the treatment of nervous complaints, where he was subjected to a prolonged course of medicinal and galvanic therapy; but, no improvement following, he became discouraged, and, having been admitted to my ward at Mt. Sinai Hospital, begged for operative relief.

The attacks were most severe in the evenings, and were readily produced by touching the lower eyelid. There was a *punctum dolens* a little above the foramen infra-orbitale. The upper teeth and palate were free, irradiation of the pain being noticed only along the tract of the supra-orbital nerve. In the absence of any signs pointing to a central cause, excision of the nerve was decided upon, and carried into effect on August 30, 1882, under chloroform.

The steps of the operation did not differ from those in Case II, except that the massive frame of the patient's head made the bone sections rather laborious. The hæmorrhage was about the same as in the former cases up to the moment when the saw, having cut through the entire superior maxilla, entered the nasal cavity, when it suddenly became very profuse. Ice-water was thrown into the nares, but failed to check the hæmorrhage, wherefore it was decided to hasten the remaining steps of the operation. The malar bone and orbital plate of the superior jaw were quickly divided. The resected parts were turned out of their bed, and then the source of the profuse hæmorrhage became apparent in a laceration by the saw of a very tardid erectile body covering the turbinated bone. The thermal cautery soon converted this erectile tissue into a dry eschar, and the operation was finished in the usual manner. The time consumed was forty minutes. Meckel's ganglion and one inch and a half of the nerve were removed. Catgut sutures and drainage, with a light compressive dressing, completed the work. The operation was followed by prompt relief. The cutaneous wound healed by first intention, no fever appearing, but the nose continued to discharge pus for a considerable time, and finally the skin became reddened over the line of section through the malar bone. A small puncture in the cicatrix being made, about three weeks after the operation, the probe detected a rough surface; and subsequently, in January, 1883, a sequestrum, corresponding to the temporal side of the section, was extracted, the defect being marked by a deeply retracted cicatrix. Up to date the patient has remained free from the facial pain.

Dr. Seessel kindly examined the nerve removed in case I, at the first operation, and also that in Case II, and found

both normal in appearance. In Case III the specimen was lost.

The proposed modifications—that is, sawing through the middle of the malar bone instead of dividing the frontal and temporal processes of the same; then, instead of v. Langenbeck's transverse, an antero-posterior (sagittal) section through the orbital plate of the upperjaw on the inner side of and parallel to the infra-orbital canal—will shorten the operation, and will materially increase the facility of access to the most central portion of the nerve.

It is far from my intention to urge the propriety of this operation in every case of supra-orbital neuralgia, and the report of my three cases in this paper was rather inspired by the desire of testing the value of a rather untried procedure, and of increasing the number of available means for combating a treacherous enemy. As long as the true nature of prosopalgia remains unknown, the employment of any means and of every means must be fair and permissible, however empirical and unscientific it may appear to be.

Book Notices.

On the Relations of Micro-Organisms to Disease. The Cartwright Lectures, delivered before the Alumni Association of the College of Physicians and Surgeons, New York, February 19, 21, 24, and 27, 1883. By WILLIAM T. BELFIELD, M.D., Lecturer on Pathology and on Genito-urinary Diseases (Post-graduate course), Rush Medical College, Chicago. Reprinted from the "Medical Record," February and March, 1883. Chicago: W. T. Keener, 1883. Pp. 131.

DR. BELFIELD's admirable Cartwright lectures are so fresh in the memories of the profession in New York, and were so fully summarized in this journal at the time of their delivery, as to preclude the necessity or desirableness of extended notice at this time. This reprint is issued in convenient size and form, and includes two appendices, but neither index nor table of contents—an omission much to be regretted where the subject is so important and the treatment so thorough. Appendix A describes organisms not treated of at length in the body of the lectures, such as *Spirillum Obermeieri*, Frisch's bacillus of *rhinocleroma*, the *Bacillus malaris* of Klebs and Crudele, bacterial forms said to be connected with the life history of syphilis, small-pox, diphtheria, typhoid fever, scarlatina, etc., *Trichina spiralis*, *Filaria sanguinis*, etc. It is well illustrated by woodcuts, after the photo-micrographs used in the lectures, a few of which are also interspersed in the body of the work. Appendix B gives a brief account of the methods especially adapted to the detection and recognition of bacterial forms.

The publisher's imprint seems to be a "paster" upon that of Trow's Printing & Bookbinding Co., of New York.

Bacteria and the Germ Theory of Disease. Eight Lectures Delivered at the Chicago Medical College. By Dr. H. GRADLE, Professor of Physiology, Chicago Medical College, etc. Chicago: W. T. Keener, 1883. Pp. 219.

DR. GRADLE's lectures, delivered at the Chicago Medical College, and here collected and published in book form, cover substantially the same ground as the Cartwright lectures of Dr. Belfield. Bacteria are here treated of first with special refer-

ence to their life history and taxonomy, and afterward in connection with the several diseases which have been attributed to their agency. Dr. Gradle has the advantage of greater space—eight lectures instead of four—and therefore, with less necessity for close condensation, he finds it possible to furnish somewhat easier reading. After discussing bacteria upon their own merits, he gives a sufficiently full account of the researches upon which is based the connection of their organisms with each disease attributed to them, and is exact and liberal in his citations of authorities. The proof is absolute, he concludes, "that the invasion by these micro-organisms is the cause of anthrax, chicken-cholera, the various forms of septicæmia in animals, tuberculosis, glanders, some forms of suppurative inflammation, malignant œdema, erysipelas, gonorrhœa, and trachoma" (p. 209). With regard to human pyæmia, relapsing fever, leprosy, typhoid fever, and pneumonia, the evidence is less satisfactory, but still inclines toward a similar conclusion. The facts are fairly stated and not at all strained toward the author's bent of opinion, and much rather out-of-the-way literature has been brought together and condensed bearing upon the supposed connection of bacteria with diseases not generally attributed to their presence—e. g., whooping-cough and poisoning with *rhus toxicodendron*. To the general student, who finds himself suffering under a certain prevailing vagueness of ideas respecting the disease-germs which are, according to Dr. Sternberg, literally in everybody's mouth, these scholarly lectures will take the place of much toilsome reading, and save an immensity of critical condemnation. There are no illustrations.

BOOKS AND PAMPHLETS RECEIVED.

The Extra Pharmacopœia of Unofficial Drugs and Chemical and Pharmaceutical Preparations. By William Martindale, F. C. S., etc. With References to their Use, abstracted from the Medical Journals, and a Therapeutic Index of Diseases and Symptoms. By W. Wynn Westcott, M. B. Lond., etc. Second Edition. London: H. K. Lewis, 1884. Pp. iv+330.

Introductory Address delivered before the Medical Class of Dartmouth College, August 1, 1883, by Louis Elsberg, A. M., M. D., Professor of Laryngology.

Medical Thoughts of Shakespeare. Compiled by B. Rush Field, M. D. Easton, Pa., 1884. Pp. 16.

Bichloride of Methylene used in a Junker's Inhaler. By J. H. McIntyre, A. M., M. D. [Reprint from the "St. Louis Medical and Surgical Journal."]

Again on Axis-Traction Forceps, and on the Basilyst. By Alexander Russell Simpson, M. D., F. R. S. E., Professor of Midwifery and the Diseases of Women and Children in the University of Edinburgh, etc. [Reprint from the "Edinburgh Medical Journal."]

FRANK P. POSTER, M. D.

NEW YORK, SATURDAY, JAN. 12, 1884.

TRICHINIASIS AND AMERICAN PORK.

COMMENTING on the recent revocation of the French decree of February 18, 1881, prohibiting the importation of American pork, the "Lancet" remarks that this action has been the result of the Consulting Committee of Public Hygiene and the Government having come to the conclusion that, with proper precautions, trichinous pork is rendered innocuous in the processes of salting and cooking. It adds that the French authorities are impressed, however, with the necessity that these precautions should be widely known and observed, and it implies that the publicity given to the matter by its having been made the subject of legislation is likely to answer the purpose of inuring such knowledge and observation. "In England," it adds, "the question interests us all the more, as the importation of American pork has never been checked. Public attention has not been awakened to the existence of this danger by any such energetic legislation, and the duty of warning the public by the ordinary channels of publicity becomes therefore especially urgent." The "Lancet" is to be commended for taking this pains to inform its readers that pork, whether American or not, should be well cooked; it would be still more to be commended if it would state how many cases of trichiniasis in England have been traced to the use of American pork, the importation of which has never been checked.

Coupled with the inference we have hinted at as fairly to be drawn from the "Lancet's" remarks, a statement lately made by our consul at Basle, Mr. Mason, becomes of interest. In a recent report to the State Department, an extract from which was published in the "Evening Post" last week, Mr. Mason says: "The fact deserves to be widely known that here in Switzerland, which is almost the only Continental country in which American meats are permitted to be imported and sold on their merits, their reputation is not only higher now than ever before, but they command a preference in this market over similar classes of meats from every other country." Mr. Mason throws out the broad suggestion that, if it had not been the case that the importation of American meats into European countries, in a normal state of the market, brought the retail price of a favorite article of food within the reach of many thousands of people who could not otherwise afford such a luxury, thereby not only making a serious competition for the European butchers and hog-raisers, but also diverting a large and constantly increasing outflow of money to the United States, it would never have been discovered by the economists of Paris, Berlin, and Vienna that American pork was dangerous or impure.

It seems that it is only for a brief period that American

pork is to be admitted into France, and only at three ports even for those days of grace. Moreover, what is graciously allowed to be landed under those terms is to undergo the further ordeal of an examination by "experts." In short, France is determined that her own hogs shall not suffer from American competition, thus following in the wake of Germany, which has declined to co-operate with our own Government in investigating the condition of American hogs. So far as France is concerned, whatever hardship her people may suffer in the future, either from the enhanced price of their own pork or from retaliatory legislation on our part, they may attribute to M. Paul Bert in great measure, judging from the reports that reach us.

It is not the province of this journal to discuss matters of legislation, except in so far as they may touch upon medicine, but we may suggest that a perusal of Dr. Miller's article on "French Brandy," published in our issue of December 8th, is enough to satisfy any Congressman's constituents that we have quite as good reasons for prohibiting the importation of certain European products as have ever been truthfully brought against the unrestricted trade in American pork.

For some time there was a lack of evidence to counteract the assertions so freely made in Europe as to the prevalence of trichiniasis in the United States, and we then expressed regret that our Government took no steps to ascertain the exact facts in the matter. Persistent and reiterated denial was certainly no valid argument to oppose to the action of foreign officials, especially as their injurious statements were supported by allegations to the same purpose made in this country. The onus seemed to rest upon us of demonstrating the harmlessness of our hog products. All that is changed now, however; the Government has gone far enough in its investigation of the matter to show that the outcry against American pork in Europe is, to say the least, founded on imaginary if not fabricated data. If the German rejection of our overtures were not enough to convince any unprejudiced inquirer of this fact, especially when taken in conjunction with the jockeying that has been found necessary to bolster up the schemes of the prohibitionists in France, its confirmation might readily be found in the condition of things in a country into which the importation of American pork has "never been checked."

THE BALTIMORE SEWERAGE CONTROVERSY.

In our issue of December 22d we deprecated the introduction of a pronounced controversial, not to say captious, element into a public discussion on various systems of sewerage in Baltimore, and we gave it as our impression that the acrimony betrayed by one of the gentlemen engaged in the discussion was founded on errors of information or of interpretation. We had reference to Dr. Chancellor's conviction that the criticism to which he had been subjected in the "Sanitary Engineer" was put forward in the interest of Colonel Waring's patented system of sewerage, and that Dr. Billings had gone out of his way to advocate either Colonel Waring's or any other special system of sewerage before the people of Baltimore.

As regards the "Sanitary Engineer," the well-known care-

fulness of that excellent journal not to suffer its columns to be used to further private ends, or even to advocate special systems not involving personal interests, should be considered *a priori* evidence that "Colonel Waring and his system" could never legitimately be read between its lines; but now we have Colonel Waring's own declaration, in a communication to the "Maryland Medical Journal," that he knew nothing about the article until he saw it in print, and a statement of his belief that, had it been written by him or in his interest, the editor of the "Sanitary Engineer" would probably have rejected it on that very account.

As for Dr. Billings, he too addresses a communication on the subject to the "Maryland Medical Journal," and in the same number we find an abstract of the lecture given by him in Baltimore. In the latter, the criticism of the Liernur system, although pointed and severe, seems to us in no wise to exceed the bounds of propriety; and in his letter, Dr. Billings's version of what he said to a prominent citizen of Baltimore after the lecture appears equally free from anything advocating a special system of sewerage for the city. In our opinion, moreover, it would have been not at all to his discredit if he had chosen to advocate either the Waring or any other tried and approved system, whether patented or not. The burden of his lecture, judging from the abstract published, was to point out certain advantages of the plan of separate conduits for the surface drainage and the sewage proper of a town under specified circumstances; and, since the Liernur system involves that plan, to that extent he surely can not be said to have spoken against it. He did allude to some of its alleged imperfections, however—chiefly its costliness.

We are glad to observe this confirmation of our suspicion that the actual facts in the case were not such as necessarily to have given rise to pique. So long as men are not charged with gross ignorance or disingenuousness, and so long as there is no occasion for such charges, it seems to us that the discussion of plans and systems of sewerage may well be allowed the widest range.

MINOR PARAGRAPHS.

THE NEW YORK STATE LUNATIC ASYLUMS.

In the annual report of the Comptroller, for the year 1883, the need of more ample accommodations for the insane of the State is pointedly referred to. It seems that the number of patients treated in the six institutions during the year was 3,684. Large sums of money have been expended to furnish the necessary increase of capacity, but in many instances not judiciously. Two examples are cited of buildings half completed at about double the estimated cost of the whole work. In view of this waste of the public funds, and to check its continuance, the Comptroller recommends that in future there should be inserted in every act authorizing the erection of asylums a clause requiring the plans to be approved by the State Board of Charities, and by his own department, before the work can be begun or the money be available for building.

THE MEDICO-LEGAL SOCIETY.

This society, which might make itself exceedingly useful, has been watched with a good deal of interest and not little

solicitude for the past two or three years by many members of the profession who, being either members generally absent from its meetings, or non-members, but yet interested in medical jurisprudence, have cherished the hope that the time would at length come when the society would cease to be vexed by the contending factions that have arisen within it. We are sorry to say that that hope seems as far as ever from realization. Last Wednesday evening, the occasion of the installation of the officers elected to serve during the year, the meeting was held, and it was followed by a "banquet," but the whole affair was preceded by a meeting called by some of the members for the purpose of organizing an opposition to the present administration of the affairs of the society. It may be that this new movement will work a radical change in their conduct. Certainly nothing short of such a change seems to us to hold out the least hope of improvement.

"THE KANSAS CITY MEDICAL RECORD."

We have received the first number of this new monthly journal, dated January, 1884. It contains forty-two large, double-column pages of reading matter, embracing original communications, clinical reports, society proceedings, selections, and editorials. Twenty-eight of the forty-two pages are taken up with selections, among which we recognize an abstract from the New York "Medical Record" (not credited) and three articles from this journal, only one of which is credited. The "Record" presents a handsome appearance, and we presume that it is only on account of the haste incident to getting out a first number that "Life's" injunction, "Render unto scissiors the things that are scissiors'," has passed in a measure unheeded. The "Record" is owned and edited by Dr. A. L. Fulton and Dr. G. Halley.

THE NOSTRUM TRADE IN PHILADELPHIA.

We learn from the "Philadelphia Medical Times" that the Board of Trade of Philadelphia Druggists has passed a resolution to the effect that its members will positively refuse to keep or deal in those proprietary medicines which are sold indiscriminately to individuals engaged in other kinds of business than dealing in drugs. This action our contemporary regards as deserving of formal notice by the medical societies. To those who can not read between the lines it would seem like a mere announcement that the druggists of Philadelphia are determined to keep the nostrum trade in their own hands, and not allow any part of it to go to the grocers.

"THE ÆSCULAPIAN."

UNDER this title Dr. Edward J. Bermingham, the editor of the "Medical Gazette," has brought out the first number of a new monthly journal. The number, dated January, 1884, contains forty-eight double-columned pages of reading matter, handsomely printed, and in every way presenting a good appearance. The original articles are two in number—one by Dr. Fessenden N. Otis, and the other by Dr. Allan McLane Hamilton. The remaining departments of the journal are entitled reviews, selections from journals, abstracts of society proceedings, and miscellany.

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 8, 1884:

also a bureau for all needed information for the sick; and they have in contemplation measures by which, if any one desires to obtain boarding in the country, or at the seaside, for cases of whooping-cough, or for recent cases of measles, scarlet fever, or diphtheria, and for information concerning all appliances for the sick, such as invalid-chairs, wheel and other crutches, bed-rests, fracture, water, or air beds, etc., he may obtain the object he seeks at the Directory.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 29, 1883, to January 5, 1884:*

APPEL, DANIEL M., Captain and Assistant Surgeon, having relinquished the unexpired portion of leave of absence granted by S. O. 68, Headquarters Division of the Atlantic, November 16, 1883, and reported for assignment, assigned to duty at Fort Porter, New York. Par. 2, S. O. 247, Department of the East, December 39, 1883.

HAVARD, VALERY, Captain and Assistant Surgeon. Assigned to duty in charge of office of Medical Director, Department of Texas, during the temporary absence of that officer. Par. 2, S. O. 164, Department of Texas, December 31, 1883.

NAVY INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending January 5, 1884:*

Hudson, A., Medical Inspector, from duty as Assistant to the Bureau of Medicine and Surgery on the 18th inst. to the United States steamer Lancaster, as the relief of Medical Inspector N. L. Bates, who is to be detached and ordered home.

RUSSELL, A. C. H., Passed Assistant Surgeon, from the Navy-Yard, Washington, to hold himself in readiness for sea-service.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, January 14th:* New York Academy of Sciences (Section in Chemistry and Technology); New York Ophthalmological Society (annual—private); New York Medico-Historical Society (private).

Tuesday, January 15th: New York Academy of Medicine (Section in Medicine); New York Obstetrical Society (private); Medical Societies of the Counties of Franklin (annual), Kings (annual), and Otsego, N. Y.; Ogdensburg (N. Y.) Medical Association.

Wednesday, January 16th: New Jersey Academy of Medicine (Newark).

Thursday, January 17th: New York Academy of Medicine (A Demonstration of Antiseptic Dressings, by Dr. Robert F. Weir).

Saturday, January 19th: Roman Medical Society.

OBITUARY NOTES.

DR. THOMAS W. PERRY, of Providence, R. I., died suddenly, on January 5th, of angina pectoris, at the office of Dr. Bowditch, in Boston. This well-known physician was born in Hopkinton, R. I., in 1823, and graduated as a physician at the University of New York in 1846. He began practice in Connecticut, afterward was surgeon of a Rhode Island regiment during the war, and finally located in Providence as a partner of the veteran Dr. Capron, who died recently. Dr. Perry had a large practice, and was much respected and beloved both as a physician and as a man.

J. WILHELM FRANKL, M. D., died on Wednesday, the 9th inst., in the forty-second year of his age. He was graduated from the University of Prague in 1867, and was a member of the Medical Society of the County of New York, the Medico-Chirurgical Society, and the Physicians' Mutual Aid Association.

Letters to the Editor.

THE NEW YORK COLLEGE OF MIDWIFERY, ITS PAMPHLET ENTITLED "WOMAN'S WORK" AND ITS "CONFIDENTIAL" CIRCULAR TO THE PROFESSION AND THE LAITY.

NEW YORK, January 3, 1884.

To the Editor of the New York Medical Journal:

SIR: When the College of Midwifery was organized we accepted the offices of censors, believing the institution and its object worthy of our recognition and assistance. Our connection with the institution had been but brief when we already found it necessary to criticise severely some things in its organization and management.

Our positions as censors gave us no voice in the conduct of the institution, our duties being simply to be present at and assist in the examinations.

The title and character of the pamphlet mentioned above met with our disapproval when first seen after it was in print, and the circulars and "confidential" card which have been distributed to the profession and laity, issued wholly without our knowledge, and only accidentally seen by us *to-day*, meet with our most emphatic disapprobation—to such a degree as to determine us to dissolve our connection with the institution, which we have done by forwarding our unconditional resignations to-day.

B. F. DAWSON, M. D.,
PAUL F. MUNDÉ, M. D.

NEW YORK, January 8, 1884.

To the Editor of the New York Medical Journal:

SIR: Will you please insert the subjoined resignations in the next issue of your journal?

[Copy.]

"HENRY D. CAREY, Esq.,

"President of the College of Midwifery.

"DEAR SIR: The Board of Trustees having persisted in issuing a circular letter and card to physicians, inclosed in the book entitled 'Woman's Work in the Field of Medicine,' which we consider extremely objectionable, and against which we protested at the last meeting of the Board, we hereby respectfully tender our resignations as members of the Faculty of the College.

"JAMES O'REILLY, M. D.,
"JOHN ALSDORF, M. D."

Yours, etc.,

JOHN ALSDORF.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

A STATED meeting was held December 11, 1883, ROBERT F. WEIR, M. D., President, in the chair.

TRANSVERSE WOUND OF AN EXTENSOR TENDON OF THE FINGER; SUTURE.—Dr. A. C. POST presented a patient with the following history: "November 3, 1883, George Moore, aged nine years, was brought to my clinic, with the index-finger of his right hand flexed at a right angle at the articulation, between the first and second phalanges. The patient had no power of extension, although there was no rigidity of the articulation. There had been a transverse incision over the back of the joint five weeks before. The external wound had healed. I made a free longitudinal incision over the dorsal surface of the finger, and found the tendon divided transversely throughout nearly its whole breadth, there being a very narrow strip undivided on each side. The proximal

end was full and loose, the distal end was somewhat atrophied, and adherent to the periosteum. I excised the margin of the opening, and then brought the divided ends together with fine sutures, after which I fixed the finger in a position of exaggerated extension to a dorsal splint, passing over the hand and forearm.

"November 10th, I dressed the wound, removed the sutures, and found the external wound almost perfectly united.

"December 8th, on removing the dressings, I found the finger straight, and the patient had the power of flexion and extension. I did not, however, allow him to make extensive movements."

NEURALGIA OF THE SECOND BRANCH OF THE TRIGEMINUS.—Dr. F. LANGE presented a patient, about forty years of age, a tailor, who suffered from neuralgia of the second branch of the trigemini, on the right side, which had resisted for a long time the usual external and internal remedies and applications, until finally the patient submitted to an operation, which was performed in March, 1882, after the method of Luecke, modified by Braun and Lossen, consisting in an osteoplastic resection of the zygomatic arch and bone, finding the nerve in the depth of the speno-maxillary fossa, at its exit from the skull, and, besides, a separation of the nerve at its exit from the infra-orbital foramen, and extracting the anterior piece from the base of the skull to this point. He was also able to destroy the speno-palatine ganglion, and so far the result had been permanent. Anæsthesia followed the operation immediately, and was complete also on the corresponding side of the palate. The patient at present had a certain kind of formication, which he described as like the crawling of worms, but had no real pain. The operation was performed by making a horizontal incision along the upper edge of the zygomatic arch extending to the external angle of the orbit, and then a perpendicular one downward over the base of the zygoma, and with a fine saw separating the zygoma from its attachment to the superior maxilla, directing the saw so that the blade was more parallel to the sagittal plane, in order to prevent subsequent disfigurement from depression of the separated bone. Then by bone scissors the arch was cut across half an inch in front of the meatus auditorius externus. This triangular flap of skin and bone was pulled downward, and then the speno-maxillary fossa laid open, the temporal muscle drawn backward, and the nerve found, after some adipose tissue had been pulled aside or removed. In the patient presented, the operation had not offered any peculiar difficulty, but Dr. Lange presumed that it was probably on account of his lack of fat, and could readily conceive that sometimes in stout, fleshy persons the operation might be very tedious. He was able to see the internal maxillary artery, but there had been no disagreeable interruption on account of hæmorrhage. The wound healed entirely by first intention, and as an accident the rubber drainage-tube was healed in. After a time the tube was cut out. The result, so far as disfigurement went, was rather gratifying, and also with respect to the recurrence of the disease. Dr. Lange did not think that any other operation afforded the possibility of excising the nerve to so great an extent and with so little danger and disfigurement as the one described. For some time the patient had slight difficulty in opening his mouth in consequence of inflammatory contraction of the temporal muscle; but at present he had no difficulty which prevented him from taking his food, though the movements of the jaw were not normal yet. The little wound by which the nerve was exposed at its exit from the infra-orbital canal had hardly left a visible scar.

Dr. C. K. BRIDDON asked what objection there was to performing the anterior operation first, and reserving the more extensive operation in the speno-maxillary fossa for a return of the disease.

Dr. LANGE said that he did not regard the operation as a severe one.

Dr. BRIDDON remarked that he saw the more extensive operation performed several years ago, and it was exceedingly tedious, and very unsatisfactory, as he thought. He was unable to state what the result was.

OSTEOPLASTIC RESECTION OF THE UPPER JAW FOR PROSOPALGIA, WITH THREE CASES.—Dr. A. G. GERSTER then read a paper with this title. [See p. 38.]

Dr. LANGE would merely say that, starting with the principle of causing as little lesion as possible, he thought the certainty with which prompt union of the wound could be expected was greater in Luecke's operation than in the one which Dr. Gerster had described, because any septic influence which might follow opening of the nasal cavity and its appendages was excluded. He also thought the thoroughness with which the surgeon was able to remove the branches of the nerve after its exit from the skull was greater in Luecke's operation than in the one described by the author of the paper. It seemed to him that it must be quite difficult to reach the speno-palatine ganglion with certainty from before, although he had not had any practical experience in the method. Finally, comparing the result of the operation in the patients presented from a cosmetic point of view, one must evidently decide in favor of Luecke's operation.

Dr. T. M. MARKOE said his experience had been limited to a single case, in which he performed the operation through the antrum. He found no difficulty in detaching the nerve from the canal in which it lay in the superior maxillary bone, and, holding the nerve with a pair of forceps, he was able to trace it back with the end of the scissors, and succeeded in cutting it off not so far back as the foramen rotundum, not so far back as the point where the two short branches go to Meckel's ganglion, but close to that point, and he felt that he cut off the nerve posterior to the two posterior dental branches, those in which relapse would seem most likely to take place. The operation was difficult and very tedious by reason of inability to get light at the bottom of the cavity. Nevertheless, he felt quite sure that he cut the nerve at the point mentioned. The result was extremely satisfactory, but the entire case impressed him unfavorably concerning neurotomy in these cases. The case began as one of neuralgia of the inferior maxillary nerve, for the relief of which he trephined the inferior dental canal some two years before, and removed about one inch of the nerve, and the cure was satisfactory. After a few paroxysms, the pain entirely subsided, but finally it returned in the second branch, the infra-orbital, and it was for the relief of this relapse that he performed the operation on the superior maxillary nerve above described. The patient was entirely relieved by this second operation, and Dr. Markoe saw nothing of him for nearly three years, when he returned, saying that he had not had pain in the region of the distribution of the infra-orbital nerve, but was then suffering intensely from supra-orbital neuralgia, and refused to take any further chances of recovery by operation. In other respects the patient was entirely healthy, and there was no reason to suspect that the affection had a central origin.

Dr. GERSTER then presented the patient upon whom he operated in May, 1881, and said he was aware that this method would rarely have to be employed, but, as it might be useful in another instance, and was adapted to the removal of the second branch of the trigemini, he thought it was worthy of the effort which it required. That was the only object which he had in bringing the operation forward. He was sure that Luecke's method was preferable in many cases, while in other cases Carnochan's method would be the better one to resort to, but there must be cases where the method which he had described would

be the best, either as the first operation to be performed, or as a last resort.

As to the question of the healing of the external wound, since the introduction of antiseptics this was of much less importance than formerly. The avoidance of an opening into the antrum was not of much advantage, as already shown by Wagner's experience, which, to be sure, was gained before the days of antiseptic precautions. What seemed to him most curious was the circumstance that, after having removed the entire nerve from the infra-orbital canal, sensation returned so quickly in those parts which were innervated by the second branch. Perhaps this might be explained by some filaments of sensitive nerve passing back by way of the Vidian nerve to the facial, and thus being distributed to the skin of the face.

Dr. W. S. HALSTED remarked that in the reproduction of almost the entire superior maxillary the infra-orbital canal might play the part of the "tubular suture" of Gurlt and Vinlair, the divided ends occupying a so-called "*Virolage*."

Dr. J. W. HOWE was unable to understand the advantages which the operation described by Dr. Gerster had over that performed by Dr. Carnochan.

Dr. GERSTER said the chief advantage which the operation had over all other operations was that it gave a great deal of space and light, and, taking all the cases together as they came, it afforded better opportunity for manipulation in the bottom of the speno-maxillary fossa.

Dr. HOWE thought there could be no great difficulty in dissecting out the branches of the nerve in Carnochan's operation, and cited one case which he had last winter. The only difficulty which he experienced was in determining whether or not he had to deal with Meckel's ganglion; and he would ask whether there was any special appearance or condition by which Meckel's ganglion could be distinguished from a little mass of cellular tissue and blood-vessels. The case in which he operated was one of seventeen years' standing, accompanied by spasmodic contraction of the muscles of the face. The pain was relieved very much for two weeks after the operation, and it then returned, but without spasm. A drainage-tube had been passed through the canal, and this was injected with a strong solution of chloral, which diminished the pain, and since that time the patient had been comparatively free from suffering—at least had no very violent pain whatever.

Dr. LANGE said that in the patient presented it was rather easy to trace the branches arising from the trunk of the nerve down to the speno-palatine ganglion, probably because the patient was a very favorable one so far as a scanty amount of fat was concerned. It seemed to him, also, that the nerve, so far as it had been exposed in the cadaver presented by Dr. Gerster, was not reached so immediately at the foramen rotundum as it was possible to do in Luecke's operation. And it also appeared to him that a few of the thin branches of the nerve were passing down which might be easily overlooked, and the nerve cut just in front of these fibers, and in that way the operation be performed less thoroughly.

The PRESIDENT said that three years ago he had an opportunity to present to the society a case of persistent infra-orbital neuralgia which had been cured by Carnochan's operation. The patient was seen two years afterward, and there had been no return of the pain. In this case Wagner's operation had been previously performed by Dr. Seguin, who had had the patient under treatment for a long time. The first operation was accomplished without difficulty, and the nerve was divided probably not much farther back than the posterior margin of the orbital plate. The patient was relieved for a time, but, as there was a recurrence of the symptoms, an opening was made by him into the antrum with a chisel, the inferior wall of the canal

opened up by means of slender scissors, and the posterior wall of the antrum broken through by the blunt end of the same instrument. The remains of what was supposed to be the nerve, but which proved to be cicatricial tissue to which the posterior portion of the nerve was attached, were seized with the forceps and held taut, and, by means of a little forked, blunt hook, carried onward to the foramen rotundum, the nerve was traced out and there divided with scissors. The operation was aided very materially by the use of reflected light from the head mirror. Healing was rapid; no constitutional reaction took place, and the deformity following the operation was very trifling indeed. In fact, he thought that the more severe osteoplastic operation should be reserved for the more obstinate cases. Carnochan's operation had advantages over that described by Dr. Gerster, and over Luecke's, in ease of performance, freedom from hemorrhage, and lessened deformity. He could conceive of the possibility of necrosis occurring after both the osteoplastic operations, and also the possibility of mastication being interfered with in Luecke's operation. Under such circumstances Carnochan's operation should be the first one to be resorted to.

The question raised by Dr. Howe was a pertinent one. The ganglion could not always be recognized. He (the President) had been unable to recognize it in his case, and other surgeons had been unable to recognize it, although the extraction was accomplished, as shown by paralysis of the palate immediately after the operation.

The President also thought it a point worthy of note that one of Dr. Gerster's cases proved the possibility of a good deal of hemorrhage, which interfered with seeing the different anatomical structures.

Dr. LANGE remarked that one advantage which Luecke's operation possessed was, that the hemorrhage was quite insignificant, and also that the disfigurement was very much less than that left after any of the other operations. He would emphasize the statement that Luecke's operation involved much less surgical interference than Carnochan's, or that by temporary excision of the jaw. There was, in fact, only the lesion of the zygoma, which was comparatively unimportant. So far as he knew, the process of healing had been favorable.

The PRESIDENT asked whether, if suppurative and inflammation should occur, there would not be more or less impairment of the muscles of the jaw.

(To be concluded.)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of December 5, 1883.

CRITICISMS ON THE SPECIFIC THEORY OF HYDROPHOBIA.—Dr. CHARLES W. DULLES read a paper with this title. [See the journal for December 29, 1883, p. 707.]

Dr. HENRY HARTSHORNE observed that the author of the paper has given an interesting philosophical analysis of the confusion and uncertainty attaching to much of the evidence concerning hydrophobia. But when the question occurred as to accepting the conclusion to which he had come—that no such specific disease, resulting in man from the bite of the rabid dog, had been proved to exist—he must necessarily dissent from this, for the best possible reason; namely, direct personal observation. It had happened to him, early in his practice, to meet with a case, the history of which was known to him from the beginning. The essential facts were these: A boy, eight years of age, was bitten, almost in front of the speaker's house, by a dog which, upon usual evidence, was considered to be mad. A day or two afterward his father brought him to Dr. Hartshorne,

and, late as it was, excision of the bitten part was advised; this was, however, not consented to. About a month afterward he was called to see him. Not proposing to detain the College with all the particulars of the case, which had been fully reported in the "American Journal of the Medical Sciences," it might be said that it was studied without any prepossession or expectation as to what its course would be. He had not, before that time, become very familiar with the clinical history of the disease. The most striking symptom which might be considered, in the speaker's present judgment, to be pathognomonic of hydrophobia in man, was an *excessive reflex excitability of the muscles of respiration*. This persisted throughout the case. Not only an effort to drink a fluid, but the sound of running water, any sudden sound, a flash of light, even the puff of air made by moving the hand lightly above the patient's face—every such slight cause would induce a *gasping* of respiration, which gave rise to incessant distress, and made swallowing food or drink impossible. The boy was violently delirious; and this, as well as his age and the peculiar character of his affection, put quite out of sight any suggestion that a *mental* cause, from horrible anticipation of hydrophobia (such as, no doubt, in several other cases had existed), could influence the case. He died in about a week from the beginning of the attack.

He also afterward saw another case; that of a man, under the care of the late Dr. George W. Norris, in one of the surgical wards of the Pennsylvania Hospital. This patient was not delirious. In him also the reflex inspiratory spasm was clearly marked, although, for a time, he could swallow moistened pellets of bread, or other solids, but no liquids. Along with this, it must be noticed, there was *in neither case* any *tetanic muscular rigidity*. The absence of this at once differentiated such cases from tetanus, with which some authors, who had not *seen* instances of hydrophobia, had been inclined to conjecture their identity.

By such observations, confirmed by the records of many others in the literature of hydrophobia (which was not *all* confusion), Dr. Hartshorne had been obliged to conclude that there was a disease *en* *generis*, to which that name, though not well chosen, might apply. Attacks did occur in men, after they had been bitten by dogs, which were unlike every other disease; therefore we inferred the existence of a *specific* malady. It was, so far (with two or three *doubtful* exceptions only), invariably fatal. It might take place anywhere, even (as Dr. Dulles incidentally said) in Constantinople and Africa, notwithstanding the denial of this by some writers.

Against the horror and certain fatality of such a disease, granting its existence, the precautions now commonly taken were not at all excessive. It would be very unsafe for them to be relaxed, unless a clear case was made out of the actual non-existence of hydrophobia. It would be much to be regretted, therefore, that a conclusion such as that of the paper just read should go before the public, in the proceedings of the College, without protest, if, at all events, objection to it rested in other minds as well as in that of the speaker.

Dr. Hartshorne, after some further discussion, inquired of Dr. Dulles whether he rejected the opinion that *rabies canina* was inoculable from dog to dog.

Dr. R. P. HARRIS said: I have met with several cases of hydrophobia, and have been present when the disease was investigated by autopsy. I well remember the case of the boy just reported by Dr. Hartshorne. The youth and sex of the patient, the peculiar symptoms of his malady, and the history of his exposure to canine rabies, gave positive proof of the existence of hydrophobia. My father, not having met with a typical case, in an extensive country practice of twenty years, was inclined to doubt the existence of true rabies until I took him to see this

case. Dr. Hartshorne was present, and we examined the patient critically, and with much interest. This was the first case my father had had an opportunity to see, although he had then been in active practice more than thirty years, and it had the effect of convincing him that he had been in error in regard to it. The existence of this disease in young subjects, of which there are many cases on record, clearly proves to my mind that it is a veritable blood-poisoning, and entirely distinct from hysteria and the other neuroses. I have known a hysterical woman, under the fear of rabies, from having been bitten by a dog, manifest symptoms somewhat allied to those of hydrophobia; but a critical examination revealed the true nature of the disease. Such a case existed some years ago in Camden, and was very much talked about in Philadelphia; but the recovery of the lady satisfied the community of the true nature of the attack.

Dr. S. W. GROSS asked Dr. Dulles if he desired to be understood as stating that hydrophobia was not a specific disease, but a pure psychosis.

Dr. S. D. GROSS inquired whether Dr. Dulles was willing to be bitten by a dog suffering from hydrophobia as a test of his belief in the non-existence of the specific disease in man.

Dr. DULLES declined at present to give an answer to the inquiry of Dr. Henry Hartshorne, because to do so would involve a discussion almost as long as that of the paper he had read. He preferred at this time to confine himself to the subject of hydrophobia as reported to occur in man.

In reply to the question of Dr. S. W. GROSS, Dr. DULLES said that if the specific element in hydrophobia were eliminated—as he believed it ought to be—there remained nothing except to consider the cases as pure psychoses, or as errors of diagnosis. It was, he said, remarkable how little physicians seemed to be aware of the number of conditions in which, as was well known to students of the subject, the symptoms of hydrophobia were simulated. In reply to Dr. S. D. GROSS, he said that the question the latter had asked proposed not so much a test of the truth of his convictions as of his personal courage, and this was not the subject under discussion. But he could say that there had been a disbeliever in the specific theory of hydrophobia who had been willing to show his faith by his works. In the beginning of this century Dr. White, a young surgeon of Brighton, England, had allowed himself to be bitten by a mad dog, and had inoculated himself with this dog's saliva, without suffering any evil effects in consequence.

ABDOMINAL TUMOR SOMEWHAT RESEMBLING PREGNANCY.—Dr. JOHN H. PACKARD read the following paper:

I venture to hope that the following report of a case, presenting some unusual features, may be of sufficient interest to warrant me in bringing it before the College:

Mrs. G., aged twenty-one, a very slim and delicate-looking woman consulted me, on the 21st of July, in regard to a slight and uniform abdominal enlargement, which had been first noticed by her shortly after her marriage about three months previously, and had been gradually and steadily increasing. She menstruated regularly every month, and had had no nausea. Neither the breasts nor the nipples showed any change from the virgin state.

There was no tenderness at any point in the abdomen, and the appearance and feel of the swelling were very much such as would be presented in the early stages of pregnancy.

On the 26th I saw her again, and made an examination *per vaginam*. The os uteri was soft, and the cervix was of some length; but there was a bulging above, as if the uterus contained a mass partly solid and partly liquid. I did not, of course, think it right at this time to introduce a sound, as, in spite of the absence of rational signs, the presumption seemed to me to be in favor of pregnancy. One fact seemed to militate against this view, viz., that she rather lost than gained flesh.

I declined to express any opinion as to the character of the swell-

ing, but told the husband that my hope was that the case would prove to be one of pregnancy, as it was likely otherwise to be very grave.

There was a good deal of pain on either side of the hypogastrium, apparently due to tension of the muscles; this was temporarily relieved by the use of chloroform liniment. She had very little appetite, and I gave her a tonic composed of nux vomica and gentian.

The swelling continued to progress steadily, and on September 13th she presented the appearance of being at about the middle of the fifth month of gestation. The hypogastric pain troubled her greatly, and was only allayed for a very short time after each application of the liniment.

At the desire of the family, I now asked and obtained the advice of Dr. Ellwood Wilson, who saw her with me on September 15th.

In the forty-eight hours which had elapsed between my previous visit and this one, a very marked change had taken place. The abdomen had become greatly enlarged, its walls forming one curve from the ensiform cartilage to the pubes; there was very decided fluctuation, and percussion showed an area of dullness which was attributed by Dr. Wilson to the existence of a cystic tumor connected either with the Fallopian tube or with the broad ligament. A sound was introduced into the uterus, the cavity of which was found to be unoccupied. Dr. Wilson advised the drawing off of the liquid, which was accordingly done, by aspiration, on the 17th. More than a gallon of ropy, yellow liquid, somewhat deeply tinged with blood, was thus removed; the flow then ceased, and the end of the cannula encountered a solid substance, apparently a septum of considerable thickness. Upon the withdrawal of the instrument, a fresh flow took place, the liquid spouting out from the orifice to a distance of several inches. When this subsided, the abdomen, which was much less tense, was covered with raw cotton, and a bandage carefully and firmly applied.

During the operation the patient became quite faint, but rallied after the administration of a little brandy and water. In the evening her temperature rose to 103.5° F., but before morning it fell to about 100°. She slept very little, and complained of much pain, due partly to the stiffening of the cotton and bandage by the agglutination of some of the liquid which oozed from the belly. On examining the wound in the morning, it was found closed.

The following evening the temperature again rose to 103.5°, but subsided again before morning, and was not thereafter above 99°. Yet her condition was unsatisfactory; her face was much pinched, and anxious; she had very little appetite or ability to take food; at times her mind wandered slightly, and she slept but little. Vomiting occurred frequently, and she was seldom free from nausea. Her bowels acted regularly; her urine was free, and normal in every respect. Her pulse varied, but was generally from 110 to 120.

Beef-tea, milk, with brandy and lime-water, and champagne, were given at as short intervals as the stomach could bear them, and at stated times. External warmth was carefully kept up. It was determined that, should symptoms of peritonitis present themselves, ovariectomy should be at once resorted to.

A portion of the liquid was submitted to Dr. H. F. Formad for examination, and his report, which was not received until some time after the case had terminated, was: "I think it very doubtful that it comes from an ovarian cyst, the fluid showing very little epithelium, and very few of the ovarian cells of Drysdale."

September 23d, her condition was very much more favorable; her mind was composed and even cheerful, her pulse and temperature good. Some food had been taken and retained.

On the 24th her state was much the same, and it was thought proper to entertain the idea of an operation for the removal of the supposed ovarian tumor. In the afternoon Dr. Agnew saw her with Dr. Wilson and myself, and it was decided that the attempt should be made on the following day.

Accordingly, on the 25th, at noon, ether was administered by Dr. G. P. Sargent, of Bryn Mawr, and, in the presence of Dr. Wilson and Dr. Agnew, I opened the abdomen by an incision in the median line. After dividing the wall I came to what seemed to be a cyst, and passed in an ovariotomy trocar, when a very free evacuation of liquid, straw-colored and ropy, but clear, took place. It was now apparent that the liquid was contained in the peritoneal cavity, and that there was a large solid

mass lying among the intestines. This tumor was soft and doughy, like a placenta; it seemed to belong to the mesentery, since, although somewhat movable, it was firmly attached to the posterior wall of the abdomen, rather high up. The surface of the mass having been slightly lacerated, there was somewhat free bleeding, which was checked with some difficulty by ligation with carbolized catgut, and by the application of a cautery-iron. The wound was now closed with two large pins and a ligature cast around them, and with metallic sutures; a sheet of raw cotton was applied over the whole belly, and secured by a bandage.

The patient rallied considerably, and, after the effects of the ether had passed off, became quite sensible; but she soon began to sink, and died on the 27th, about forty-eight hours after the operation. No autopsy could be obtained, so that the exact nature and connections of the tumor must remain a matter of conjecture.

The notable points in the case now detailed seem to me to be the occurrence of a solid tumor, probably of malignant character, and apparently connected with the mesentery, in a young woman recently married; its resemblance in its physical appearances to the pregnant womb; the very sudden change that took place by a fresh effusion into the peritoneal cavity, and the obscurity which even then existed as to the real nature of the case. Even with the most accurate diagnosis, effective treatment would have been out of the question, and I can not but think that my suspicion of pregnancy, erroneous as it proved to be, really prolonged the patient's life, which would have been almost necessarily sacrificed by earlier interference.

THE REPORT OF THE COMMITTEE ON METEOROLOGY AND EPIDEMICS, for the years 1881 and 1882, was then read by Dr. JOSEPH G. RICHARDSON.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held December 12, 1883, Dr. GEORGE F. SHREADY, President, in the chair.

ANOMALIES IN THE DEVELOPMENT OF THE LIVER.—Dr. F. FERGUSON presented three specimens of anomalous development of the liver, and referred to other cases which he had met with. Perhaps the form of anomalous development first in the order of importance was that in which the right lobe was much larger than normal, often at the expense of diminished size of the left lobe. It might extend down to the crest of the ilium, and, being club-shaped, constitute an apparent tumor in that region which was liable to puzzle the diagnostician. Moreover, it might cause pressure upon the ureter, or ascending colon, and interfere with the function of those organs. The next in order of importance was the hypertrophied or enlarged left lobe. This form he had sometimes found developed at the expense of the right lobe. It was liable to be mistaken for a new formation. A third anomaly was the presence of but a single lobe. Dr. Ferguson had seen only one example of this kind, in which the liver formed almost a perfect hemisphere. A specimen was presented, composed of one large lobe with four small ones on its lower surface. Of this form he had seen two or three examples. Another form was that in which the liver was divided by a large number of sulci, segregating numerous small lobes, in one of the specimens presented reaching as high as twenty in number, and in another specimen to a still greater number. The condition was not due to disease.

PYOSALPINX.—Dr. Ferguson also presented specimens removed from a patient with the following history: She was twenty-two years of age, married, a housekeeper. On the 27th of November last she was suddenly seized with acute pain in the chest, and suffered from dyspnea and vomiting, in which condition she entered the hospital a few hours later. She had had dropsy for some time, and had been in a hospital for the relief of that symptom. On admission, the face was cyanosed, there was dyspnea, she complained of pain in the chest, the

respiration was rapid, and the temperature was elevated, but not above 103° F. at any time. There was a loud blowing murmur heard at the base of the heart. The urine contained albumin. Death took place some hours after admission. At the autopsy there was oedema of the legs below the knees, the peritoneum contained twelve ounces of serum, there was no evidence of peritonitis, there were indications of pleurisy with some effusion, there were extensive vegetations on the mitral valves, and dilatation of the cavities. The lungs were markedly oedematous and congested; the liver contained fat; the spleen was larger than normal, pigmented, and congested; the stomach and intestines were congested in places. The left kidney was slightly larger than normal, and the seat of chronic diffuse nephritis; the right was markedly atrophied. The bladder and uterus were normal; the ovaries were displaced downward and forward, and retained by adhesions. The Fallopian tubes were the seat of pyosalpinx, the right containing a greater amount of purulent fluid than the left. On microscopical examination, numerous ciliated columnar cells were found in the fluid removed from the Fallopian cysts.

DERMOID CYST SUSPECTED ON MICROSCOPICAL EXAMINATION OF THE URINE.—Dr. C. HEITZMAN presented a specimen of urine which he regarded as coming from rather a unique case. Last year a physician brought him a specimen of urine which had been passed by a woman about fifty years of age. Every two, three, or four weeks she passed an enormous quantity of whitish lumps with her urine, accompanied by excruciating pains. The specimen which was brought him looked floccy, and presented a glassy, shining appearance. Under the microscope it proved to be composed almost entirely of horny epidermal substance, with a comparatively large number of crystals of urate of sodium in the form of sheaves. The microscopical symptoms pointed to a dermoid cyst, which from time to time discharged its contents into the pelvis of the kidney. He expressed the opinion that, if the patient suffered great pain and her health was being impaired, it was advisable to cut down and remove the cyst. He had heard nothing further of the case until about two weeks ago, when her physician wrote that the patient's condition continued the same as it had been for the past thirty or forty years, with rupture of the supposed dermoid cyst every two or three weeks. Aside from this fact and the presence of laryngitis, and, at times, of hemorrhoids, the patient was in good health.

VALUE OF THE ELASTIC LIGATURE.—Dr. J. A. WYETH presented the remains of the isthmus of an enlarged thyroid gland which had been successfully brought away by an elastic ligature wound around it several times, and fastened by adhesive plaster to the integument of the throat. The ordinary ligature had previously been tried, but had broken down and led to hemorrhage. The goitre had been removed successfully by excision.

ANGIOMA OF THE RIGHT VOCAL BAND.—Dr. L. ELSBERG presented the specimen, which had been removed about a week before from the right vocal band, near the anterior commissure, from a man, twenty-eight years of age, whose profession was that of a vocal teacher. In the mirror the tumor appeared to be of the size of a large pea. It was dark in color, rather soft to the probe, and microscopically presented a spongy appearance, being largely composed of blood-vessels and some connective-tissue elements. This was the second specimen of the kind which Dr. Elsberg had seen, and there were in all literature only about ten cases on record of angioma of the interior of the larynx. The majority occurred on the right vocal band near the anterior commissure, a fact which possibly could be accounted for by the distribution of the blood-vessels.

A STATED meeting was held December 26, 1883, Dr. GEORGE F. SHRADY, President, in the chair.

DILATATION OF THE STOMACH.—Dr. JOHN C. PETERS had recently seen a case of very great distension of the stomach, in which the patient, a woman, retained food for two or three days and then vomited it up in very large quantities in a pretty thoroughly digested condition. A small tumor could be felt, supposed to be in the neighborhood of or at the pylorus. These symptoms had existed between eighteen months and two years. The patient was greatly emaciated, but was not cachectic. She was so feeble that he did not consider it safe to introduce the œsophageal tube. This was the third case which he had seen of over-distension of the stomach, due to a tumor, all occurring in females.

Dr. VAN GIESON recalled a case of enormous distension of the stomach, which had been seen by Dr. Flint, who believed it to be due to stricture of the intestine. The patient became progressively emaciated, and at the autopsy the dilatation was found to have been due to paralysis. There was no stricture or tumor.

Dr. PETERS added that the patients whom he had seen suffered a great deal of discomfort on being turned from side to side.

Dr. R. W. AMIDON had seen three cases of supposed dilatation of the stomach, in two of which he had introduced the œsophageal tube on two different occasions, but had never been able to withdraw anything but mucus. The patients were greatly emaciated. No autopsy had been made.

FLOATING KIDNEY.—Dr. AMIDON also mentioned having seen a patient whose condition suggested the question whether floating kidney was usually attended by albuminuria.

Dr. G. L. PEABODY said that, out of a great many autopsies, he had not seen a single instance of true floating kidney, and he was, therefore, inclined to doubt whether all cases diagnosed to be such during life would stand the test of a post-mortem examination. At any rate, there had not been a sufficient number of reliable cases reported to enable us to generalize with regard to the usual condition of the urine.

ENDARTERITIS OBLITERANS IN EPITHELIOMA OF THE PENIS.—Dr. PEABODY presented a portion of the penis, amputated for epithelioma, the interest of which centered in a condition which he had now seen in three cases of epithelioma—namely, endarteritis obliterans. The patient was a man, seventy-one years of age, who, two years ago, first noticed a small pimple, which was painful, on the lower aspect of the foreskin. The pimple continued to grow, and three months ago ulcerated. The penis was then removed. The lesion to which he would call attention was first noticed in the arteries of the brain, and was then believed to be due to syphilis. Dr. Peabody, however, had seen it in the lungs in cases of chronic phthisis, in chronic nephritis, and in epithelioma in non-syphilitic subjects. On the intima of the blood-vessels was to be seen fully formed connective tissue occluding their caliber.

Dr. AMIDON had observed a similar condition in a case of sarcoma of the humerus in 1879, but, as attention had not then been called to the true pathology, he had regarded it as due to secondary deposits.

MILIARY ABSCESSSES OF THE KIDNEYS WITHOUT KNOWN CAUSE.—Dr. BEVERLEY ROBINSON presented a specimen which had been removed from the body of a domestic, twenty-one years of age, who was admitted to Charity Hospital, August 31st, in a condition of emaciation and of pregnancy at about the third month. She complained of incontinence of urine and of pain on passing it. Within a few days irregular sweats and chills developed, there was vomiting, and the urine was full of pus. October 21st, when transferred to the medical ward, her condi-

tion was very bad indeed; she weighed only about eighty pounds. There was almost constant vomiting, and there was pain on pressure over the region of the kidneys. She miscarried October 24th. Immediately after the miscarriage she seemed to do well, but began to vomit during the night, and died in a condition of exhaustion soon afterward. At the autopsy the lungs were found to be oedematous, with some adhesions at the posterior aspect of the right apex. The heart was normal. The liver weighed seven pounds, and contained fatty deposits. The spleen was congested. The kidneys weighed nine ounces each, and their surfaces were studded with milary abscesses. The bladder was normal. There were no tubercular deposits anywhere to be found, nor were there metastatic abscesses elsewhere than in the kidneys.

PERFORATION OF THE PLEURA.—Dr. ROBINSON also presented a lung with the pleura removed from a patient who had suffered from pleurisy and chronic phthisis. There was an opening from the lung into the pleura at a point of old adhesion, which, by its valve-like form, showed the possibility of a communication existing between the lungs and the pleural cavity without there being an interchange of fluids.

In the absence of a microscopical examination, Dr. PEABODY was disposed to look upon the first specimen presented as one of tuberculosis rather than of milary abscess.

PYELO-NEPHRITIS.—Dr. J. A. WYETH presented the kidneys, ureters, and bladder of a man who died in his twenty-sixth year. He had been in good health up to two years ago, when he came to Dr. Wyeth with hemorrhoids, of which he was cured. About three months later he returned, complaining of frequent desire to pass water. After six months' duration of this symptom he began to have elevations of temperature, and there were certain signs of hectic. Slight consolidation was discovered at the apex of either lung. He was sent to the hospital, where he died. The specimens showed the anatomical changes of pyelo-nephritis and chronic cystitis very well. One of the ureters was markedly dilated. The bladder symptoms had been so much more marked than those of the kidneys that three weeks ago Dr. Wyeth attempted the operation of cystotomy. Some time before, when operating for hemorrhoids, he had given ether, which the patient took badly, it being necessary twice to resort to artificial respiration. On the present occasion, when about to do Thompson's operation of cystotomy, he gave chloroform. He had scarcely made an incision through the skin when the pulse flagged, the heart stopped, and respiration ceased. A blow over the heart started that organ, and, after about five minutes' artificial respiration, the breathing went on regularly. The operation was not completed. In the light of the autopsy, doubtless the operation would have done no good had it been completed. Disease of the kidneys had only been suspected. He inquired what had been the experience of those present regarding the value of cystotomy in chronic inflammation of the bladder. Sir Henry Thompson had spoken very favorably of it. Dr. Wyeth had had two cases in which he had thought of doing the operation. He would prefer the lateral incision.

Dr. J. P. GARRISH had done the operation once with good results.

Dr. PEABODY thought that the question of eliminating disease of the kidneys was a more important one to solve, on account of its difficulty, than that of drainage of the bladder.

The President thought that pyelo-nephritis and the accompanying danger of administering an anæsthetic would contraindicate cystotomy.

Dr. WYETH thought that, while pyelo-nephritis rendered cystotomy less likely to prove successful, he would prefer to give the patient the benefit of the chance, notwithstanding the greatness of the risk.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

A STATED meeting was held January 3, 1884, the President, R. A. CLEEMANN, M. D., in the chair.

OÖPHORECTOMY.—Dr. E. E. MONTGOMERY corrected a statement made in the report of the case of oövariectomy narrated by him at the meeting of December 6, 1883. [See the journal for December 22, 1883, p. 698.] *Silk ligatures*, not catgut, were used to tie the pedicles. The convalescence of the patient had been very satisfactory. The temperature did not rise above 99° F. In performing this operation no antiseptic was used, but all instruments, sponges, etc., were washed in boiling water, and boiled water was used in washing the wound and abdominal cavity. The mental condition of the patient was such that she was kept constantly under mechanical restraint, and on one occasion when she had been left alone for a few minutes she tore all the dressings off the wound, and at the next visit it was found bare, but no bad result followed. The sutures were removed on the eighth day. Some pain in the lower part of the abdomen and slight fever began on the twenty-fifth day, but she had since improved again. Her mental condition was at present better than it had been for a year before the operation, and she could now converse rationally.

SEPTICÆMIA AFTER ABORTION.—Dr. W. H. PARRISH reported the following case: A young woman, twenty years of age, came into the Philadelphia Hospital in the finishing stages of an abortion, which had been coming on for some days. The cause was unknown, but was probably instrumental. At the time he first saw her, three days after her admission, her temperature was 103° to 104° F., and her pulse 150. She had had a chill before admission, her abdomen was distended and tender, and the uterus was very sensitive. The right parotid gland was swollen and painful. It continued to enlarge, and, fearing septicæmia, he gave fifty grains of quinine daily by the rectum, as the stomach was too irritable to retain it; one ounce of whisky was given by the mouth every hour, day and night. A small quantity of morphine was given to relieve the abdominal tenderness. The pulse and temperature fell rapidly, but the gland continued swollen and painful; it was quite hard, but was discolored. There were no chills now, but, fearing the presence of pus, he made an opening by Hilton's method, incising the skin and using a director to tear an opening through the gland tissue. This opening was enlarged by passing a pair of forceps, closed, along the groove of the director, and withdrawing it opened. The opening gave exit to two or three fluidrachms of pus. The gland now improved in appearance, but another abscess opened behind the gland and discharged freely. The two abscesses did not communicate. The patient was now convalescent.

OFFICERS OF THE SOCIETY FOR 1884 were then elected as follows:

President, RICHARD A. CLEEMANN, M. D.; *Vice-Presidents*, B. F. BAER, M. D., W. T. TAYLOR, M. D.; *Secretary*, W. H. H. GITHENS, M. D.; *Treasurer*, ALFRED WHELEN, M. D.; *Librarian and Curator*, T. HEWSON BRADFORD, M. D.; *Councillors*, R. P. HARRIS, M. D., LEWIS D. HARLOW, M. D., WILLIAM GOOD-ELL, M. D., T. M. DRYSDALE, M. D.; *Publication Committee*, JOHN H. PACKARD, M. D., JAMES V. INGHAM, M. D., ELLIOTT RICHARDSON, M. D., B. F. BAER, M. D.

W. H. H. GITHENS, M. D., *Secretary*.

THE PROPOSED MARINE HOSPITAL ON STATES ISLAND is meeting with the usual opposition shown by the people of a neighborhood in which the establishment of a hospital is contemplated. Although not unnatural, this feeling is altogether unjustifiable, and we can not suppose that in this instance it will be accounted as of much weight.

Reports on the Progress of Medicine.

MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

BY GASPAR GRISWOLD, M.D.

THE ACTION OF CONVALLARIA MAJALIS.—Dr. George Herschell ("Lancet," Oct. 27, 1883) describes a case in which bad effects followed small doses of the tincture. The patient was suffering from a moderate degree of cardiac weakness and irregularity, without any ascertained organic lesion. He had been taking digitalis for some time with more or less benefit, when the author determined to try the effect of convallaria. He began with five minims of the tincture, three times a day, but was obliged to stop after a few doses on account of the remarkable effects produced. Almost immediately after each dose the pulse became nearly imperceptible at the wrist, and the patient suffered from a sense of oppression over the sternum, nausea, cold feet, vertigo, and a feeling of utter prostration. These symptoms lasted two hours and then subsided, only to reappear when the next dose was taken. The patient again improved when the convallaria was stopped, and digitalis given in its stead. This case is interesting from the fact that all writers on convallaria have especially emphasized the view that no unpleasant symptoms are to be feared from its use, and that no toxic effects have been observed. It is also interesting to observe that the same patient, who was so unfavorably affected by convallaria, was subsequently much benefited by digitalis. This would seem to indicate that these two drugs are far from being identical in their action.

THE CHEMICAL NATURE AND PHYSIOLOGICAL ACTION OF NITRO-GLYCERIN.—Dr. M. Hay ("Practitioner," June, 1883) quotes the conclusion of Dr. Weir Mitchell and Dr. Reichert that nitrite of amyl has the same action as nitrite of sodium or potassium. Since nitrites of bases so different as amyl from sodium or potassium act alike, the inference is unavoidable that the action of all three depends upon their common factor, nitrous acid. Now, nitro-glycerin acts almost exactly like nitrite of amyl, and yet nitro-glycerin is classed by all chemists as a *nitrate of glyceryl*. To clear up this apparent inconsistency, the author has made experiments which prove that, although nitro-glycerin in itself contains no nitrous acid, yet nitrous acid is formed by decomposition if nitro-glycerin is mixed with defibrinated blood. The inference is, therefore, that nitro-glycerin acts as a *nitrite* by virtue of nascent nitrous acid which is developed on mixing nitro-glycerin with blood. Dr. Hay finds that nitrous acid does not, as Gamgee believed, form a compound with hæmoglobin; on the contrary, it merely induces the further oxidation of hæmoglobin into methæmoglobin, a chocolate-colored substance with a characteristic spectrum. The author believes that the physiological action of the nitrites (including nitro-glycerin, which acts as a nitrite) is in some way an outcome of their chemical relations with hæmoglobin.

INTRA-PERITONEAL INJECTIONS OF ALBUMINATE OF IRON FOR ANÆMIA.—Professor A. Vachetta ("Gazzetta degli Ospitali," May 2, 1883) proposes the intra-peritoneal injection of the albuminate of iron as a means of curing chronic anæmia. He recommends that two grammes of the albuminate of the ammonio-citrate of iron be dissolved in five cubic centimetres of cold distilled water, filtered, warmed, and injected with a Pravaz veterinary hypodermic syringe. The point of selection at which to puncture the abdominal wall is usually taken near the umbilicus. The author made numerous experiments upon animals, and was much gratified with his results. He never observed the least peritonitis as a result of the operation. There were

iron and some albumin for a short time to be detected in the urine. The color of the red corpuscles became more vivid, and their number was increased with striking rapidity. The author recommends the procedure as safer and better than Ponfick's intra-peritoneal injection of blood, and advises a trial of it in cases of extreme and obstinate anæmia.

INTRA-PERITONEAL AND INTRA-VEINUS INJECTIONS FOR CHOLERA.—Dr. B. W. Richardson ("Med. Times and Gaz.," Aug. 4, 11, 18, 25, Sept. 1, 1883), in a paper on feeding by the veins and on intra-peritoneal injection in the collapse of cholera, first notices the remarkable effects which have so often followed the intra-venous injection of warm saline solutions. The fact that the stimulation in these cases is only temporary he explains on the ground that saline solutions contain no food elements, and suggests the following solution as a substitute: White of egg, four ounces by weight; common salt, one drachm; phosphate of sodium, one scruple; clarified animal fat, one ounce; pure glycerin, two ounces; water to one pint. *Preparation:* Dissolve the salt and phosphate of sodium in the water, and, having well whipped the albumen, add it also to the water. Place the mixture on a water-bath, raise to 135° Fabr., keep stirring, and digest at this temperature for one hour. This constitutes an artificial serum. Melt the fat in the glycerin, and add to the serum at 120°. Cool to 80° and filter. The fluid thus obtained is pinkish, saline, and of a specific gravity of 1.038. It dissolves semi-fluid blood with great readiness. It takes up one third more caloric than water in the same time, and, in cooling, it restores nearly one third more. It should be injected into the veins very gradually. The best apparatus is a large funnel connected with the cannula in the vein. In this way there is no danger of introducing air, and the fluid can be introduced steadily, the pressure being modified by raising or lowering the funnel. Syringes are poor instruments of transfusion.

Dr. Richardson maintains that the operation of peritoneal transfusion was originally proposed by him, his views being entirely based on physiological research. He found that distilled water, warmed to the temperature of the body, might be injected, without the slightest danger, into either the peritoneal cavity or the cellular tissue of warm-blooded animals, provided that the quantity injected was less than one fifth the weight of the animal. When the body was greatly reduced by the removal of fluid, the absorption of the injected water took place with astonishing rapidity. The practice was tried in two cases of cholera in man, in the author's service. In one case, eight pints were injected into the peritoneal cavity; in the other, ten pints. In both cases the patients recovered; but in neither was the collapse so complete that recovery might not have occurred if the injection had not been made.

The author cites many cases in which he has personally observed remarkable restorative effects produced by injections of water and of saline solutions into the veins and into the peritoneal cavity. He regrets that the improvement in these cases was usually only temporary, collapse being again produced by the causes which had induced it originally. The solution the preparation of which he describes he does not seem to have had an opportunity of using as yet, and he recommends its use on theoretical inferences based on an extended experience.

METALLO-THERAPEUTICS.—In a paper on "metallo-therapy" ("Arch. of Med.," Oct., 1883), Dr. G. Peckham calls attention to the fact that in France its claims are sufficiently well recognized. This is apt to be overlooked in this country, where very few know what the term metallo-therapy means, and no interest is taken in the subject. In Paris, the investigations of Barq and the corroborative labors of Charcot and Vigouroux have widely disseminated the details of the subject, and every one is familiar with them. Taken together, they form one of the most

striking and singular chapters in the history of medicine. The term metallo-therapy, in the sense in which it is at present employed, includes the whole subject of modifying sensibility and other nervous functions by the local application of pieces of metal, magnets, electric currents, etc. Charcot has applied the term *athésio-gènes* (sensation producers) collectively to all the agents employed in metallo-therapy, and this new word has become incorporated with the literature of the subject. A great deal has been written, in a more or less vague and desultory way, about the effects of metals locally applied, but the subject was first formulated and brought practically before the profession by Dr. Burq a few years ago in Paris. He found that certain patients affected with different degrees of anesthesia, from numbness of a hand or finger up to complete hemianesthesia, had their symptoms relieved by the application of a metallic disc to the affected part. Some patients were benefited by copper, others by silver, still others by gold, etc., each having, however, a special metal which was most active in his particular case. In one case anesthesia of a hand was entirely cured by wearing a thumb of the active metal; in other cases, rings, bracelets, and so forth, were successful. Hysterical attacks were also prevented or cut short, as in the case of Pauline at the Hôpital Cochin. This patient was hysterical and subject to violent paroxysms, ending in unconsciousness. These attacks were almost instantaneously cured by the application of a disc of copper to the epigastrium. The subject was further pursued at La Salpêtrière by Dr. Burq, and finally, in 1876, a commission was appointed by the Société de Biologie to study the effects produced by the application of metals to the cutaneous surface, and to report. The commission consisted of MM. Charcot, Luys, and Du Montpallier, and they reported to the society, on April 14, 1877, as follows: 1. The application of certain metals to the skin of hysterical and anæsthetic patients, and in several cases of organic lesions, determines important modifications, of which the principal is the return of general and special sensibility. 2. All patients are not susceptible to the same metal, gold, iron, and copper giving results, positive or negative, according to the patients submitted to experiment. 3. The patients feel at first a prickling sensation at the point of application; this is followed in a few minutes by a return of sensibility in a zone more or less extended about the point of application. 4. The anesthesia is not cured, but rather *displaced*—appearing at the corresponding point on the other side of the body and returning to its original site when the metal is removed and the experiment is ended.

A great deal of skepticism has been excited by these reports, partly because the facts were in themselves unusual and hard to believe, but mainly because the patients were nearly always hysterical women. There has been, on this account, a tendency from the first to interpret the phenomena described as dependent rather upon the imagination of the patient than upon an influence actually exerted on the nerves by metals. These objections are answered as follows: 1. The application of metallic discs appeals less to the imagination than almost any other form of treatment. Less imposing than the buzz of the faradaic battery, less impressive than a collection of galvanic cells, it has still had effects where these had been persistently tried in vain. Patients often say: "You do not expect these (referring to the discs) to do any good?" 2. Healing often occurs when both patient and physician least expect it. Experimenters have applied a metal, thinking that they had a certain one when they had another, and have discovered their mistake only when they found that the usual effects were wanting. 3. Patients in Germany, France, England, and America, and in widely different circumstances, have described the same sensations and experienced the same results.

No satisfactory theory has yet been advanced to explain the phenomena of metallo-therapy. Experimenters talk about the electric tension of parts being modified by the proximity or contact of substances to which they happen by their peculiar constitution to be susceptible, but the explanation is neither very clear nor very satisfactory. Schiff has proposed a molecular theory, in connection with which he assumes that the nerve molecules of hysterical patients are abnormally mobile, and that, in the course of the nerves supplying the anæsthetic parts, there are abnormal vibrations of molecules which disturb and prevent the normal conduction of impressions. He fancies that the approximation of a metal exercises a determining influence upon these erratic molecules and holds them, at least temporarily, in an equilibrium which restores their power of conducting sensations. This theory has the negative merit of being so far beyond our conception of tangible things that we can not refute it.

Whatever may be the theories, the facts of metallo-therapy seem well established, and, if hysterical patients can derive some benefit from this treatment, they are certainly entitled to it, and are likely to fare better than when subjected to frequent hypodermics of morphia and inhalations of chloroform.

HABITUAL CONSTIPATION.—Dr. J. M. Granville ("Brit. Med. Jour.," May 26, 1883) describes three varieties of habitual constipation which he is usually able to relieve without using the ordinary aperients, and gives the prescriptions which he commonly employs in their treatment. He first calls attention to a form of constipation in which the muscular layer of the bowel is at fault, and the presence of ingesta does not excite it to contraction. In these cases there is apt to be much discomfort from eructations, incarcerated flatus, and colicky pains. It is worse than useless to employ ordinary aperients in such a condition as this; they only irritate, without strengthening, the nerves, on whose healthy activity everything depends. When, therefore, there is this form of constipation present, the author gives the following prescription, and with very uniform success: *R* Sodii valerianatis, gr. xxxvj; tinct. nucis vomice, 3j; tinct. capsici, ℥ xlvij; syr. aurantii, 3jss.; aquam ad. 3vj. *M. Sig.* 3ss. in water, t. i. d., half an hour before meals.

In a second form of habitual constipation the difficulty seems to result from a deficiency of glandular secretion, generally, throughout the intestine. This is manifested by a peculiarly dry and earthy character of the dejecta, and is treated by the author as follows: *R* Aluminis, 3ij; tinct. quassie, 3j; inf. quassie, 3vj. *M. Sig.* 3j, t. i. d., after meals.

The third form of constipation depends upon a failure to cultivate regular habits of defecation. This may generally be relieved by directing a regular attempt to go to stool, and by the use of the following draught, taken immediately after rising—not after waking. It will be observed that it is not an aperient in the ordinary sense of the term. It is, as a rule, neither necessary nor desirable to continue taking it for more than a fortnight. In most instances it will be found to re-establish a normal habit in a week or less: *R* Ammonii carbonatis, 3j; tinct. valeriane, 3j; aq. camphoræ, 3v. *M. Sig.* 3j immediately after rising.

LEAD POISONING.—Dr. H. von Wyss ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," xlii, 1, 1883), as a result of some experiments upon lead poisoning in animals, finds that the metal has great affinity for muscular tissue. He fed a dog for a year upon small quantities of lead, varying from one to three grains daily, and using the acetate mixed with the dog's food. After death, the different tissues of the dog were subjected to a careful quantitative analysis, with the following results: Twelve grammes (3ij) of brain contained no trace of lead; 20 grammes (3j) of liver contained a slight trace of lead; 21 grammes (3v) of kidney contained a slight trace of lead; 43 grammes

(3 xj) of bone contained a slight trace of lead; 55 grammes (3j 3vj) of muscle contained one centigramme and a half (one fourth of a grain) of lead. This dog was so thoroughly poisoned that there was a blue line upon the gums for months before death.

INVERSION IN CASES OF APPARENT DEATH.—Dr. Henry R. Silvester, in a paper on the inversion of patients in apparent death from chloroform, drowning, etc. ("Lancet," May 19, 1883), argues, on physiological grounds, that this proceeding is injurious: In the first place, because it has a tendency to increase the engorgement of the right side of the heart and large vessels; in the second place, because inversion must be useless as a means of forcing on the general circulation, since the heart is unable to act on account of pulmonary congestion, and the distension of its cavities is only aggravated by the inverted position; thirdly, the venous blood sent back to the head by gravitation only deepens the coma which already exists. The best position for the patient during efforts at resuscitation is flat upon the back, with the head and shoulders very slightly raised. This position is favorable for the relief of congestion of both head and lungs; both sides of the chest are free to expand, and the circulation is restored most readily.

New Inventions, etc.

THE SILK CATHETER.

The silk catheter, referred to in the clinical remarks by Dr. Robert F. Weir, published in the last issue of the journal, page 16, is deserving of a more explicit description than could be given under the circumstances which called for a mention of it.

The accompanying cut shows that the catheter is similar in form to the ordinary cylindrical French or English instrument.

Unlike either, however, it possesses the combined advantages of flexibility quite equal to that of the rubber catheter, a much greater durability than either the French or the English instrument, and an entire absence of the swelling after it has been used, which always renders the rubber one useless in a comparatively short time. The two latter qualities have been tested by the daily use for over six months of the same catheter in an individual case.

Another and a very important quality is the extreme smoothness of the eye, which is woven (selvaged) in the catheter, instead of being punched or cut out, as in the ordinary ones.

As a drainage-tube it is superior to those of rubber, in that it will not become brittle and break, as the rubber tubes are quite apt to do. The sizes range from 5 to 12, English scale, and can be obtained from Mr. W. F. Ford, of Messrs. Caswell, Hazard & Co., under Fifth Avenue Hotel.

A GYNÆCOLOGICAL AND OBSTETRICAL SOCIETY has been organized in Paris.

Miscellany.

THERAPEUTICAL NOTES.—*Physiological Properties of Maltose.*—In a note to the Paris Academy of Sciences, M. Bourquelot ("Gazette hebdomadaire de médecine et de chirurgie") refers to a previous paper in which he had insisted on the alimentary importance of maltose—the sugar which, it is known, is formed in large quantities in the digestion of amylaceous substances—and had made the provisional supposition that this sugar was directly assimilable. But this hypothesis, resting solely on the resistance of maltose to the digestive ferments of certain animals, and on the fact of its fermentation in the presence of yeast of beer, was not sufficiently justified. M. Bourquelot has therefore been continuing his investigations to determine whether it is borne out by the manner in which maltose comports itself in the system, or whether, as is granted in the case of cane sugar, it is entirely transformed into glucose before passing into the blood. Although, as regards the diastase of malt and of the saliva, it has been asserted, contrary to the conclusions of Brown and Heron, that the prolonged action of these ferments causes the transformation of a certain proportion of maltose into glucose, the question arises whether, in the absence of all germs, these ferments really cause this transformation. Two-per-cent. solutions of pure maltose, added to diastase in solution or in saliva, previously filtered by means of the apparatus of Klebs and Tiegel, were kept at temperatures of 16° and 38° C. (the latter being slightly above the normal temperature of the body). No change was observed in the saccharine matter, even at the end of twenty-four hours, nor was there any separation of it if the experiments were conducted in the presence of carbonic acid. Invert sugar, as has been shown by Méring, has no action on maltose; but, although neither the diastase of the pancreas nor the invert sugar of the intestinal juice has, singly and alone, any action on maltose, it was necessary to determine whether, as they are mixed in the intestine, they may not transform it. Experiments showed that such was not the case. Furthermore, maltose resists artificial gastric juice, and even the pancreatic juice obtained by macerating the gland in water, unless the action is prolonged for more than six hours. If the experiment is continued longer, small quantities of glucose are formed. However, the liquid becomes filled with bacteria, a complication that can not well be prevented, as pancreatic juice will not bear filtration through porous earth. Intestinal juice, even more than pancreatic juice, becomes filled with bacteria rapidly. Collecting after a time in a flocculent mass, they fall to the bottom of the vessel. These microscopic organisms, if not a cause of error, are at least a cause of doubt as respects the conclusions to be drawn from the results obtained. When the intestinal fluids are not filtered, they transform maltose and saccharose, sometimes in part, sometimes entirely. These results are in accord with Brown and Heron's. When, however, the intestinal fluids are filtered with Klebs's apparatus, in most cases there is no transformation, either of maltose or of saccharose. Rarely, traces of glucose may be discovered. Nevertheless, in the case of maltose, the change of any part of it into glucose may be attributed to errors of manipulation.

It is interesting to know whether the acids that are formed in the stomach are able to transform maltose, under the conditions in which they act in physiological digestion. A one-per-cent. solution of maltose, added to a twenty-per-cent. solution of hydrochloric acid, at a temperature of 38° C., was unchanged after a period of thirty-six hours. Lactic acid, under like circumstances, failed to produce any change in maltose. On the contrary, when saccharose was subjected in the same way to the action of hydrochloric acid, seventy per cent. of it was transformed at the end of six hours, and ninety per cent. at the end of twelve hours. In the presence of lactic acid, saccharose to the extent of thirty-three per cent. was changed in thirty-six hours.

In view of these facts, M. Bourquelot concludes that it is not easy to maintain that saccharose is converted solely in the small intestine, and not to admit that the hydrochloric and lactic acids in the stomach may be important factors in its digestion. Furthermore, if small quantities of cane sugar pass into the blood-vessels, we may suppose that the carbonic acid constantly formed in the blood may be sufficient for

its transformation. On the contrary, maltose is not transformed anywhere in the alimentary canal except in the intestine. The question remains whether its transformation there is due to a ferment; if it is, this ferment must be different from that of yeast, the latter being without action on maltose, and it is of such a nature that it will not pass through porous earth; if not, the transformation is the result of the action of bacteria.

The Treatment of Cardiac Dropsy.—Dr. James Braithwaite, of Leeds, England ("Lancet," Nov. 17, 1883), calls attention to the fact that in the treatment of cardiac dropsy the infusion of digitalis possesses far greater efficacy than the other preparations of that drug. He does not pretend that there is anything new in this point, but mentions it for the reason that, in the region in which he lives, at least, digitalis is very rarely prescribed in that form in which its diuretic action is most marked. "I have taken the opportunity of asking various medical men about their use of digitalis," he says, "and have only met with one who uses it in infusion." In a case of extreme anasarca from cardiac disease, seen at the request of a brother practitioner, the first words of the latter, when they had withdrawn for consultation, were: "Well, I suppose you will say that it is a case in which no good can be done." He was much surprised at Dr. Braithwaite's reply: "On the contrary, I think it a very promising case." And the sequel proved the correctness of this prognosis. Dr. Braithwaite's custom is to prescribe the infusion freshly prepared each day. "I generally order half a small or medium-sized leaf to be infused, with the addition of a little black tea in about twelve ounces of boiling water, and taken daily. By this means we get the full diuretic effect of the drug in addition to its action on the muscle of the heart." The patient must, of course, be given absolute rest. This treatment, which Dr. Braithwaite has used invariably for a period of fifteen years, has yielded results that he regards as most satisfactory, although "some of the cases have been very remarkable." He does not, however, rely on the digitalis sold in the shops, but, once a year, during some country journey in autumn, collects a quantity of leaves and dries them for use.

Turpentine in the Treatment of Aneurysm.—In the journal for December 8, 1883, mention was made (p. 646) of the use of turpentine in secondary syphilis and in phagedenic sores following fever, as employed by Deputy Inspector-General Nicholson, M. D. Dr. Nicholson reports ("Medical Times and Gazette") a case of aneurysm in the popliteal space in which marked benefit followed the administration of turpentine, which was, however, given for an entirely different purpose. The patient was a man of fair frame, but thin. The aneurysm was of about the size of a swan's egg, fluid, but not pulsating. (The femoral artery had been compressed for a month or more by a well-fitting compressor in Scarpa's triangle.) The arterial tension, as indicated by the pulse, was low. The patient had been put on a spare diet. Constipation having supervened, a turpentine enema was given for its relief. The next morning the aneurysm had become firmly solidified. He says: "On the third afternoon, however, when I left, it had become fluid in its upper part, to the amount, say, of rather more than a teaspoonful. I heard nothing more of the case, except that some time afterward the limb was amputated above the aneurysm. The coagulating power of turpentine had been known to me, but, when giving it inwardly, I was not prepared for such and so sudden an effect in an aneurysm at rest. No doubt I should have followed up the enema by giving turpentine by the mouth, but, the result being an apparently firm solidification of the tumor, and it being to me a wholly new experience, I waited too long. I venture, however, to think that the result is worthy of being borne in mind in any similar case, and bettered."

ON SUTURE OF BONE IN TRANSVERSE FRACTURE OF THE PATELLA.—This procedure (fastening the fragments together by means of silver wire) was fully discussed at a recent meeting of the Société de Chirurgie ("L'Union médicale," Nov. 16, 1883). M. Chauvel had collected the statistics of forty-three cases in which the method had been adopted, and in which the mortality was about five per cent. All but four of them had occurred since the commencement of the Listerian era. In twenty-five cases, the fractures were recent. The chief danger arose from the necessity of opening the knee joint. In his opinion this operation ought never to be performed excepting when coaptation was

absolutely impossible in any other way. M. Lucas-Championnière thought that, with the observance of strict antiseptic precautions, suture of the bone might be safely resorted to immediately after the occurrence of the fracture. He cited seven cases brought before the London Chirurgical Society by Mr. Lister, "all of which were more or less successful." M. Richelot considered that in fractures of the patella the knee joint was more frequently disabled through atrophy and paralysis of the triceps, caused by arthritis, than as a direct result of the injury; and he therefore recommended electrical treatment of the muscle before resorting to a hazardous operation merely in order to bring the pieces together. The weight of opinion expressed by the four other gentlemen, whose observations are reported, was decidedly unfavorable to "immediate arthrotomy." M. Verneuil declared that, in his own case, he would not allow Mr. Lister himself to perform it. In his treatment of fractures of the patella, even when complicated with wounds, he had obtained excellent results, when the triceps was in good condition, from a simple plaster-of-Paris *attelle*, with three India-rubber drainage-tubes, and ten *agrafes*, and he had found that a ligamentous union was quite sufficient. He desired to enter his formal protest against the adoption of extreme measures for the relief of a condition which in itself was unattended with danger to life.

THE VALUE OF TAXIS IN INTESTINAL STRANGULATION.—At the recent meeting of the French Association for the Advancement of Science ("Revue de chirurgie," Nov. 10, 1883), M. Henri Henrot reported two cases of intestinal strangulation—characterized by excessive pain, constipation, and the discharge of gas *per anum*, together with a well-marked abdominal tumor and symptoms of peritonitis—in which the performance of taxis, after producing a loud pathognomonic gurgle, caused the entire subsidence of the tumor. These results, semiologically considered, were regarded by M. Henrot as showing that taxis, when methodically performed, in combination with electrical stimulation of the rectus abdominis (the resistance of the abdominal walls having been previously overcome by the aid of morphine or chloroform), would afford indications sufficiently precise to justify an immediate resort to the knife should the foregoing expedients prove unavailing. The process is carried out in the following manner: The surgeon compresses the tumor with both hands, at the same time thrusting his fingers gently and gradually, but as deep as possible, into the abdomen; he then bears upon the most prominent portion of the tumor, while he directs his efforts toward the supposed situation of the inaccessible constricting ring. The earlier the attempt is made, the greater will be the chance of success. M. Verneuil remarked that the taxis was a very delicate and dangerous operation, scarcely to be ventured upon by unpracticed hands. He was much afraid that, if adopted by the bulk of practitioners, who had not M. Henrot's experience and ability, it would result in evils even greater than those which followed its too prolonged employment in cases of hernia.

"HAMMER-TOES."—According to M. Blum, in a paper read before the Société de Chirurgie ("Revue de chirurgie," Nov., 1883), this malformation, when not hereditary and congenital, makes its appearance at the adult period of life. In three cases of the kind which he had examined after amputation of the limbs, he had found a collection of serum, with inflammation, under a corn on the dorsal surface of the second toe joint, together with a cord-like thickening of the articular capsule—this latter being evidently a secondary lesion. Rejecting the theory which attributes the affection to the pressure exercised by short shoes on second toes of preternatural length, M. Blum regarded it as due to a peri-arthritis resulting from the irritating influence of a neighboring corn. M. Terrier referred to the cases, omitted by M. Blum, in which the deformity was hereditary without being congenital. In such instances it occurred at the age of twelve or fourteen years—often upon both extremities. The speaker had known a family in which every other generation only was thus afflicted. He believed the *orteil en marteau* to proceed from an innate tendency the manifestation of which was delayed for some time after birth. M. Sée remarked that the corn was merely a secondary and consecutive phenomenon. M. Després had known the malformation to be developed at six, seven, and eight years of age, without apparent cause, there not being even a corn to account for it.

ANTISEPTIC DRESSINGS

AS THEY ARE USED AT THE NEW YORK HOSPITAL.*

By ROBERT F. WEIR, M. D.,

SURGEON TO THE HOSPITAL.

ALTHOUGH but comparatively little of novelty to hospital surgeons can be presented this evening, yet it has been thought that a demonstration of the antiseptics now in use in a large hospital would be not uninteresting to the profession at large. It is in this belief, therefore, that I venture to appear before you. Nevertheless, while there may appear differences in details between the dressings now used and those formerly resorted to, yet it must be firmly kept in mind that the principles embodied in the dressings remain the same as when first set forth by their promulgator, the too imperfectly honored Sir Joseph Lister, whose successful labors in saving life appear to us on this side of the Atlantic worthy of higher recognition than the baronetcy which has just been bestowed upon him.

What we still aim at in the treatment of wounds is to place the divided or injured parts in such a condition as to permit of the best possible drainage, and to keep them at rest as long as may be without frequent renewals of the dressing; and, for the accomplishment of the latter end, we are forced to use such chemical substances as will prevent decomposition. Notwithstanding the desire to avoid the theoretical portion of this subject, one can not escape the conviction that the development of micro-organisms is associated with putrefaction as a cause or immediate concomitant effect. Although much light remains to be shed on sundry points—such as whether one variety can develop into another, whether the poisonous action of germs differs with their growth, and what soils are most favorable to their increase, etc.—yet the prime fact above mentioned is now unquestioned. Somewhat recent investigations, it is true, have shown us that micro-organisms are to be found at all times in the air-passages and the intestines, but the researches of Lister have also taught us that the living tissues have considerable power to resist the development of such germs. This fact explains away the objection so often raised that every scratch should give rise to septicæmia. When, however, the tissues became unhealthy or abnormal, a better soil, so to speak, is furnished for the growth of the micro-organisms. What constitutes the change in the internal organs, however, is yet an unknown quantity. Externally, we can appreciate it easier. A contusion, a laceration, or the damage done at an operation brings about such alterations in the tissues as to impair their antagonizing power, and also to furnish a fruitful soil for development.

It is the aim of antiseptic surgery to neutralize such favorable conditions for germ development. This has been

best done until recently by means of carbolic acid and iodoform.

The details regarding these substances I will not again go over, but would simply say that neither the carbolic gauze of Lister nor the improved gauze of von Bruns, in which castor-oil is used as a substitute for paraffin, is free from the objection that the carbolic acid which it contains has such strong volatile properties that the material, if not used when fresh, is an uncertain staff for the surgeon to lean upon. It will also be remembered that one of the great objections brought against the use of both carbolic acid and iodoform, a still more recent antiseptic, was that they were liable to produce toxic effects, and our surgical literature is studded, and not very sparsely either, with cases in which fatal or alarming complications have occurred from this source. It was for this reason that I welcomed an antiseptic which was more potent, safer, not volatile, and easily obtained everywhere; I refer now to corrosive sublimate. Since I first became acquainted with the excellent antiseptic qualities of this salt, a year ago last March, I have been using it constantly; and it is this personal experience, corroborated by witnessing its effects in the hands of other surgeons while I was abroad this spring, which leads me to present it again to you to-day, and to recommend its virtues. In the north of Germany corrosive sublimate has come to displace iodoform and carbolic acid almost entirely; iodoform, however, is used to some extent in southern Germany, particularly in Vienna; but the healing of wounds I found was more satisfactorily produced in the hospitals of Kiel and Hamburg under the sublimate dressings than anywhere else that it was my good fortune to visit.

Corrosive sublimate is kept in contact with wounds in four or five different ways. Gauze, cheese-cloth, or mull, for instance, is impregnated with this antiseptic, and applied in several layers over the line of union of a wound just as the carbolic or iodoform gauze is employed. We endeavor to increase the absorbing power of this gauze by getting rid of the oily matter in it by boiling it in a weak solution of either soda or muriatic acid, then washing it again in water and drying it. Lately we have succeeded in obtaining it already prepared from the manufacturers.*

But, in order to make an equable pressure upon the tissues as well as to avoid a too frequent change of the dressing, which is apt to occur with gauze alone, materials of greater absorbing power and softness have been resorted to. In this connection peat immediately comes into one's mind. This substance, which I now show, was first employed, mixed with iodoform, at Kiel, and it is there to-day preferred as an absorbent material, the only change in the manner of employment being that with the white peat the German surgeons at present mix some of the black sort, which is more carbonaceous, and, like charcoal, is somewhat antiseptic; one part by weight of the black peat is mixed with four of the lighter colored. I do not think that its advantages over the white are great, although Neu-

* Read before the New York Academy of Medicine, January 17, 1884.

* Chuck & Bros., 71 and 73 Greene Street, New York, who furnish it at four cents a yard.

her places some importance upon it. One of the great advantages of the peat dressing, as pointed out by the latter surgeon, is the fact that it permits of a long period of perfect rest without disturbance by a change of the dressing. I saw patients in his wards who had worn the peat dressing without change for forty-two days. I have myself not felt disposed to leave a dressing on for so long a time as this, for I think that the tendency to septic absorption has usually passed away by the tenth to the fifteenth day, and that there is nothing to be gained by leaving the dressing on for a longer period. Another greater objection to the peat and other absorbent dressings is that they are so bulky as to prevent the easy use of splints, and, hence, in the case of compound fractures, etc., I feel a desire to inspect the parts, to determine the position of the bones, etc., more frequently than once in two, three, or four weeks. In many other cases, however, the long-continued dressing is of great value.

Some time ago we were in the habit of using in these wards a substance obtained from an Indian tree known as jute, employing it carbolized. But it was found that the carbohc acid rapidly disappeared, even more so than from the Lister gauze,* and the dressing therefore fell into disuse, to be revived again, however, when corrosive sublimate came into notice. While abroad I saw a preparation of jute which it would seem would meet any one's ideal. Here is a specimen of the old and of the new kind which I would call your attention to; you will observe that the first specimen, although the best to be obtained in the market here, contains many coarse fibers, and is quite harsh and ropy; the other is free from these faults, and is very soft and silky, and extremely comfortable to the patient. We have still another substance which perhaps absorbs better than any of these; for this also we are indebted to the Germans. I do not know that it is made in this country. This was imported from Tübingen.† It consists of the pulp of wood manufactured into a cottony form for ready conversion into paper. It is capable of absorbing thirteen and a half times its weight of water, while jute has the power of absorbing only four to six, and peat nine or ten times its weight of water.‡ While, therefore, wood-wool has greater absorbent properties than any of the other substances mentioned, it has an advantage over peat in being more cleanly. It is also easy to obtain, and costs here eight cents a pound. It is also mixed with the peat. Neither it nor peat, however, is so soft and easy to a wound as jute.

Lastly, there is a substance which may be used for this purpose, but which I have just tried—a substance which those practicing in the country certainly can always obtain—namely, the ordinary moss of the woods. It requires to be

dried in an oven to kill the insects found in it. It is soft, and has strong absorbent powers; it will take up about four times its weight of water. I am disposed, from its softness and elasticity, to think that this substance would be found to be next to jute as a dressing, and after it wood-wool and peat.

All these substances are prepared for use in a very simple way. The jute and moss are dipped into a solution of corrosive sublimate, 1 part to 1,000 of water, and 50 parts of glycerin. They are steeped all night in this, then wrung out, and allowed to dry in as far as the presence of the glycerin will permit.

The gauze and cotton batting, deprived of oily matters, are immersed in a little different solution, viz.: Corrosive sublimate, 20 parts; water, 4,480 parts; glycerin, 500 parts, which is a one-quarter-per-cent. solution. A slight aniline tinge is given to the gauze to distinguish it from the unimpregnated material. These are the solutions now used in Schede and Kümmel's wards at Hamburg, being somewhat different from those I published last winter. I will only add, it is desirable to have these preparations somewhat freshly made, as often slight deterioration occurs from the change of the bichloride into calomel.*

At the time of the operation a solution of corrosive sublimate—1 part to 1,000 of water (sometimes 1 to 2,000)—is allowed to trickle slowly, but nearly continuously, over the incision.† It is made to run so freely at some of the clinics in Germany that the surgeon and the assistants wear not only a rubber operating coat, but also rubber shoes, in order that they shall not be swamped with the fluid. In order to protect the patient from this deluge, an ingenious device of rubber cloth is resorted to, which you see here. The limb is passed through a hole in a large rubber sheet, which is tightened by a purse-string of rubber tubing, and the upper half of this sheet is then thrown back on the patient's body, as is shown in this drawing, which I have taken from Neuber's work, "Antiseptischen Wundbehandlung," 1883.

The bleeding vessels are tied, not with catgut made according to the Listerian method, but by being put in a bichloride solution—1 part to 100 of water—for ten minutes, and then in a watery solution of 1 to 1,000 for ten to fifteen hours, and afterward wound on bobbins and kept in absolute alcohol. This makes a much better ligature than when the catgut is prepared according to the formula given

* This is easiest tested by dropping some lime-water on the dressing. If a yellow spot is seen, bichloride is yet present; if a black spot appears, calomel has formed.

† In operations involving the thoracic and abdominal cavities the carbohc spray continues to be employed.

* See the "New York Medical Journal" for January, 1880.

† Peat, wood-wool, and deacidified drainage-tubes are imported by M. Lieman, 2 Jones Lane, New York. The sublimate gauze, cotton, and catgut are excellently made by an Ende, of Hoboken, N. J. Peat costs six cents a pound, wood-wool eight cents, and fine jute forty cents.

‡ Walcher. "Mittheilungen aus der chirurg. Klinik zu Tübingen," 1882. Neuber, however, says that peat absorbs sixteen times its weight of water, and wood-wool only eight times its weight. ("Mittheilungen aus der chirurg. Klinik zu Kiel," 1883.)

last year, and which was formerly used in Germany. According to that method, the catgut was kept in a solution of sublimate in alcohol and glycerin, which made it unsatisfactory. We also sometimes make use of the ligature prepared according to the method of Kocher, of Bern—namely, first putting the catgut into the oil of juniper twenty-four hours, and afterward into absolute alcohol. Both of these kinds of catgut are great improvements on the oily catgut of Lister, not slipping, and being much easier to handle, as well as more satisfactorily antiseptic. The chronic-and-sulphurous-acid dry catgut of Lister has been found to be too hard and insoluble, and has therefore been discarded. The possibility of absorption of the corrosive sublimate solution causing toxic effects has been kept in mind, and has led some to the use of a milder antiseptic, such as that suggested by Thiersch, of Leipzig, which, consisting of boric acid, 6 parts, salicylic acid, 1 part, and water, 500 parts, is called the boro-salicylic solution. This is allowed to flow over the wound in the course of the operation, the final washing being made with the corrosive-sublimate solution. Schede, however, informed me that he had employed the corrosive sublimate solution in over a thousand cases, and had found toxic effects in only three or four instances, and then only as a stomatitis or a diarrhoea, not requiring the dressing to be abandoned. I myself have not seen, so far, any poisonous effect from the use of the sublimate solution. It sometimes causes a slight erythema around the edges of the wound, but no more so than do carbolic acid and iodoform, and not so much as does subnitrate of bismuth, which is an antiseptic that has recently been introduced to us by Kocher, of Bern, but which, unfortunately, has no control over erysipelas.

All hemorrhage having been checked and the parts cleansed, you proceed to sew up the wound, using catgut, not silk, for this purpose. If silk be used, it must have been previously impregnated with the corrosive sublimate. Instead of the ordinary interrupted suture, the continued suture is what is now employed, and, if it is necessary to recross the stitch, no disadvantage results from that fact. There must be sufficient space left to admit of an ordinary rubber drainage-tube, or that introduced by Neuber, made of decalcified tubes cut out of bone. You can make them, however, of chicken-bones, for instance, by placing such in dilute muriatic acid until only the soft part remains. In cases of amputation, or wounds where it is important to get primary union, it is desirable to use these decalcified tubes, as, in the course of four or five days, the major portion of them will have been absorbed or dissolved, making it unnecessary to remove the dressing in order to get rid of the tube, which we are obliged to do when the rubber drainage-tube is employed. One objection to the bone tube is that it often becomes absorbed too quickly; * to obviate which Küster, of Berlin, keeps it in absolute alcohol before use. All these preparations you will see on the trays passing around. Having cleansed the wound carefully by squirting the sub-

limate solution through the drainage-tube, you place over it several sponges to firmly compress it, and then take a piece of sublimate gauze, called a handkerchief technically, clap it over the center of the wound, and with it, in lieu of the sponges, make considerable pressure, and over that place half a dozen more pieces, in each instance renewing the pressure over the face of the wound. Then, over the central portion, you may apply either more of these handkerchiefs, or a compress of several thicknesses of sublimate gauze. The gauze should not be in too damp a condition, in order that, when the bandage is applied and firm pressure made, it may retain a degree of elasticity and better secure rest. In Hamburg they resort to a refinement which I do not use, because it is believed to be unnecessary—that is, they place along the line of the sutures a layer of spun glass immersed in the sublimate solution, in order to prevent possible over-action of the antiseptic, and also, because of the capillary action of the fine glass, to cause ready absorption of the blood which may ooze forth during the first twenty-four hours. This refinement has also been abandoned in other portions of Germany. Kümmel, who employs the glass-wool in the manner just alluded to, is also accustomed to using twisted or braided glass to take the place of the drainage-tube. I do not think it possesses any advantage.

To return to the dressing: after securing your handkerchiefs over your wound by a few firm turns of sublimate gauze bandage, you apply your absorbent dressing, consisting of peat, wood-wool, or whatever it may be, done up in bags of suitable size and shape. These bags are from one to two inches thick, and tacked together in a number of places to preserve an even thickness. You may apply three or four smaller ones, adapting them about the wound, and then a larger one over these, and bind all firmly with a crinoline bandage dipped in the antiseptic solution, tucking sublimate cotton under the free edge, where needed. I pass a sample of these different dressings to you that you may appreciate their relative weight and softness. I think you will be struck at once with the fact of the superiority of the jute dressing. We do not use any impermeable substance on the outside of these dressings, as is done by Lister, as a precaution against the volatility of his carbolic acid. That is not necessary in the more permanent dressing; moreover, the pads are very thick, and the discharges do not readily reach the outer surface. There is, moreover, an objection to the impermeable outer covering, in that it not only preserves the moisture of the dressing, with which it is employed, but it also retains the perspiration which takes place in the limb, and thus acts too much as a poultice.

If you find that on the second or third day there is no elevation of temperature, you may consider that your patient is doing well. If you find a slight staining from the discharge coming through the dressing, just douche the parts with the bichloride solution, and apply over the place an additional mass of sublimate cotton or gauze, and let matters go a day or two. In other words, we do not change the dressing until we find some decided signs that things are going wrongly. In fact, Esmarch told me that he did not consider a mere elevation of temperature of itself to in-

* Another is that, when kept in carbolic oil for some time, they become too soft. They can be hardened by placing them in alcohol and glycerin, equal parts, adding to the mixture half a grain of sublimate to the ounce.

dicate the need of change in the dressing. I should not be inclined to accept that view, but should consider an elevation of temperature persisting for twenty-four hours a sufficient reason for removing the dressing and searching for the cause.

On account of the action of the bichloride solution upon metals, we are still in the habit of immersing our instruments in a five-per-cent. solution of carbolic acid.

These remarks would not be complete without some words with regard to attention to cleanliness on the part of the operator and the assistants. You know that a good deal of importance has been and is placed upon cleanliness; it is even considered by some as the principal feature or secret of the antiseptic treatment. It is true that cleanliness will accomplish a great deal. One must candidly admit this, especially after reading about or witnessing the results of the treatment of Mr. Lawson Tait, of Birmingham, who may fairly be called the apostle of cleanliness. Not only does his published account of a hundred ovariectomies, performed with but few antiseptic precautions and in which there were only three deaths, entitle him to this distinction, but also does his recent oral statement that this year nearly 250 abdominal operations of various kinds had been accomplished with much the same diminished mortality. When I visited his wards there were seen seven cases of ovariectomy, three hysterectomies, one of opening into the gall-bladder, and two of exploratory incision, the patients in each of the cases doing well so far as progress toward recovery was concerned, though stitch-abscesses were not infrequently met with, and the incisions themselves were not so neatly healed as those seen in Czerny's wards at Heidelberg, and there were more temperature oscillations of moderate range than were seen elsewhere under antiseptic dressing. His hospital was the cleanest private hospital that I ever was in. He has only one assistant besides the etherizer. His instruments were few and simple, and kept in trays under water. He said he kept them submerged because they were easier to handle, and blood adhered to them less tenaciously. I would say here, in passing, that in Germany I was told that they flooded the floors of the operating-rooms to prevent dust and germs from flying about. I noticed, too, that Mr. Tait took his dozen sponges home with him, and I asked him the next day at his house what he did with them. He replied that either he or his wife personally cleaned them. The sponges were first put for twenty-four hours in running water, afterward, for another twenty-four hours, in a solution consisting of one pound of carbonate of soda to four gallons of water; then cleansed in water, dipped in a five-per-cent. solution of carbolic acid, dried, put in rubber bags, and hung up in the laundry. Though the results attained by rapidity of operation, experience, and great cleanliness may, in the hands of a Tait, justify the diminution of antiseptic precautions in abdominal operations, yet that surgeon himself admits that the experience of men great in other departments of surgery has shown the advantages of antiseptics. To the ordinary surgeon, I believe that asepsis can be easier carried out than continued cleanliness, and will in the end give better results, as it is the essential something added to cleanliness.

I have, however, purposely dwelt upon the care of the sponges, because these are very commonly neglected even by those using antiseptics. It is, unfortunately, thought that carbolic-acid and sublimate solutions can be relied on to kill off every germ that may come in contact with them; unwise risks are therefore taken in many ways, and often sponges, hastily washed out in water and half filled with fibrin of the blood, are replaced in the jars containing the disinfecting solution; and the surgeons themselves, disdaining a clean muslin or linen operating-gown as too butcher-like, insist on retaining what ostensibly are their ordinary coats, but in reality are those worn at many operations, as the splashes of dried blood and pus on them clearly show. In addition, the caution must also be given that, although increased security is furnished to the surgeon by the expert use of antiseptics, yet it is unwarrantable to expect success in every case, or to take injudicious risks on the strength of their employment. Mishaps will continue to occur, often from the surgeon's own fault, and at times in spite of all his care.

In Kiel, Hamburg, and Halle, whence our best surgical statistics are obtained, beside the cleanliness of the operating-room, gowns, and sponges, special care is taken to inculcate this valuable lesson by the public and thorough washing of the hands and nails of the surgeon and his assistants, and also by the scrubbing the skin of the patient with soapsuds (at Kiel an iodoform solution is then painted on), at the site of the intended operation. In the New York Hospital, prior to an operation, not only are the parts washed with soap and water, but also with a mixture of turpentine and alcohol, two ounces to the pint, both as a solvent for greasy matter and likewise as a penetrating antiseptic—turpentine being a germicide even in so weak a solution as one part to seventy-five thousand.

The sponges in our hospital, as in Germany, after proper cleansing, are kept in an antiseptic solution for a week before they are again used. To carry out this plan we have, as can be observed, on a shelf in the amphitheatre, a row of glass jars, seven in number, representing the days of the week. The sponges are, in the first place, prepared in the following manner: After getting rid of the sand by shaking and beating them, they are thoroughly washed in warm—not hot—water, for if hot water is used it deteriorates the quality of the sponge substance and tends to fix the dirt within its meshes. This is particularly so if the sponges have already been used at an operation. The sponge is then placed in a 1-to-1,000 solution of permanganate of potash for twenty-four hours. If the permanganate is found to be losing its beautiful pink color, a little more may be added. At the end of this time the permanganate of potash is washed out with warm water. The sponges are now bleached by immersion in a solution composed of one part of sulphite of sodium to one hundred parts of water, to which has been added a one-fifth part of a watery solution of hydrochloric or oxalic acid of a strength of 8 parts to 100. They are stirred up with a stick for a few minutes, until they whiten; if left longer, they will become friable. Then they are washed out with water again, and left for some time in running water. The sponges are afterward put

into a carbolic-acid solution, 1 to 20, or in a solution of 1 to 1,000 of the bichloride of mercury, and kept there until used. Sponges so prepared, such as we use at this hospital, cost but about one cent and a half each; and at that price they may be thrown away after use at an operation. This is my custom in private practice; at the hospital it is the rule that, if the operation is one upon the rectum, the vagina, or other parts where contamination is likely to take place, the sponges used are afterward destroyed; in amputations and other cleanly operations upon the otherwise healthy subject, the sponges are cleansed for subsequent use. In all abdominal operations new sponges are employed. The sponges that are to be again used are washed thoroughly in running water, and afterward kept for some hours in a weak carbonate-of-soda solution, to dissolve out the fibrin, etc., and then placed in the antiseptic solution as before. Such are the antiseptic dressings used at this hospital in the wounds to which they are applicable; there are certain wounds of the body, as of the mouth, rectum, and elsewhere, in which it is necessary to employ iodoform, which is better adapted to such localities. If you have no other preparation at hand, you can rub the iodoform into the ordinary gauze or simple mosquito-netting, and apply it to the wound. The sticky iodoform gauze is readily made by rubbing iodoform into the ordinary Lister gauze. Iodoform also makes the best application for small lacerated wounds. But remember that more than forty-five grains will give rise to symptoms of poisoning.

Finally, the principle of rest should be carried out thoroughly. No matter how small the operation—as, for instance, the removal of a small tumor from the ankle—the limb is placed in one of the easily cleaned enameled-iron guttered splints of Volkmann's pattern, and held immovable until healing is accomplished or the risk of inflammation has passed away.

Such are the details of the management of wounds and injuries which at the present time seem best to fulfill the conditions demanded by an antiseptic treatment. It is hardly to be expected that the general practitioner will have at his command all the materials here shown. He can, however, have sundry powders of corrosive sublimate, of eight grains each, in his possession, and, when called to a case of injury, can rapidly add a pint of warm water to one of these powders, bathe the wound freely with the solution, dip into it some cheese-cloth, or, what is even better, ordinary absorbent cotton,* then squeeze this out as dry as possible, or, if time allows, partially dry it by exposure to heat, and apply it to the wound. Drainage can always be accomplished with rubber tubing perforated in the ordinary manner, choosing, when possible, the black or red rubber for the purpose. This dressing, duly secured with a bandage dipped in the same solution, will answer for a first application, and permit you to prepare a more elaborate antiseptic appliance if you wish.

Now, does all this carefulness of detail "pay," to use the phrase of the day? The gynecologist who, in 1877,

* This, according to Neuber, takes up fifteen times its weight of water.

told me I would surely kill my patient if I did a contemplated ovariectomy under antiseptics, not only was wrong, for I succeeded, but he himself has recently advocated, with all the force of his great name, the use of antiseptics to the fullest degree in the lying-in chamber; and the most distinguished surgeon of our city, who opposed Listerism when first presented here,* is now one of its most strenuous advocates.

To further express the value of an antiseptic treatment, I shall only allude to a very few facts bearing on this point. It is like discussing a self-evident proposition, but, as there are always some doubters, I beg to take some figures from our midst. Prior to the use of antiseptics the mortality from compound fractures of the arm, forearm, thigh, and leg was over thirty-three per cent. in the Roosevelt and St. Luke's Hospitals; in the old New York Hospital it amounted to sixty per cent.; in the Boston City Hospital, to forty-one per cent. This was under the old treatment of poultices, salves, fracture-boxes, etc. Under the open treatment, with such counter-openings as were necessary, the mortality, in the best hands, dropped to twenty-six per cent. Under antiseptic treatment, I have had 118 major compound fractures, with 8 deaths, a mortality of six per cent. Up to my seventieth case I had not had a single death, but, in endeavoring to treat by this method some of the severer forms of compound fractures from railroad accidents, I lost several patients, and spoiled my record. Lately I have had twelve cases of compound fractures treated with the sublimate dressings, without a single death.

Similar testimony is to be had in connection with amputations. Billroth's statistics are here extremely valuable, giving the experience of a skilled surgeon with various methods of treatment—where, in other words, the personal equation remains the same. This surgeon, from 1860 to 1867, with the open method of treating wounds, had a mortality in amputations of 35.1 per cent. From 1868 to 1875 he continued to use the open treatment, and from 1875 to 1876 he used the wet masses of carbolicized or thymolized lint and jute, with a mortality of 29.5 per cent. From 1877 to 1880, under a strict antiseptic treatment, the mortality went down to 5.7 per cent.†

Volkmann,‡ too, in 261 amputations, had only 14 deaths, which is a five-per-cent. mortality; and 108 of these healed by first intention, a condition which I had only seen once prior to the use of antiseptics. Neuber§ records also 105 capital amputations, with a mortality of 7.6 per cent. As a tribute to the latter surgeon's permanent dressings, it should be stated that in four of his cases only one dressing was used. Still more satisfactory is the employment of the permanent or peat dressing in 49 knee-joint resections, in 36 of which the dressing remained unchanged from the time of the operation until the parts were healed. He attributes his greater success in getting union in resections

* "On the Antiseptic Treatment of Wounds and its Results," by R. F. Weir, M.D., "New York Medical Journal," December, 1877.

† "Die Amputationen an Professor Billroth's Klinik, 1877-'80," Wölfler, 1882.

§ "Eine neue Amputationsmethode," G. Neuber, 1868.

than in amputations to the imperfect apposition of the muscular structures in the latter operation; and, in amputations, he therefore recommends the separate suturing of the muscles with catgut, under which procedure he got primary union in thirteen out of fourteen cases in which he tried it.

In my own practice, I find notes of thirty-five amputations without a single death, viz.: 1 hip-joint, 7 knee-joint, 7 thigh, 9 leg, 7 arm, and 2 forearm amputations. Two deaths following amputation for compound fractures have already been counted under those injuries. Should such be placed also in the list of amputations, the result would be 37 cases with 2 deaths, a mortality of 5.4 per cent.

With such results, I feel that I shall be pardoned for repeating words used on a former occasion, but now employed with a conviction deepened by increased experience: that "the saving of life which is thus indicated, occurring as it now does or ought to do over the whole world, should entitle the name of Joseph Lister to outrank in medicine all of his century, not excepting the discoverer of anæsthesia."

LATERAL URETHRAL STRICTURE; ITS DIAGNOSIS AND TREATMENT.

By JOHN A. WYETH, M.D.,

PROFESSOR OF SURGERY IN THE NEW YORK POLYTECHNIC; SURGEON TO MT. SINAI AND ST. ELIZABETH HOSPITALS.

Lateral urethral stricture, that is, a cicatricial contraction following an inflammatory process on any portion of the urethral circumference and not involving the whole, is a condition admitted by surgeons almost without exception.

Though writers lay great stress upon the fact that the urethra normally is not a cylinder, but a collapsed tube, the walls of which are in contact, all of which is true when it is at perfect rest, yet, when it is serving its function as an outlet to the urine or the prostatic-seminal fluid, it is a cylinder and nothing else; nor is it less so when, in the hands of the surgeon, it is explored by instruments of precision and treatment.

When it is in use, it is a cylinder; when it becomes of interest to the surgeon, it is a cylinder; practically, it is always a tube, and not one which is collapsed. A lateral contraction may occur in this tube—a cicatrix on one side or segment of its circle-wall—just as at the mouth, where the cicatrization and contraction are lateral after a burn on one side of the face.

I propose to show that lateral strictures do exist, that they may be recognized and located, and that the cicatrix itself may be divided, not cutting blindly into the floor or roof of the urethra, as advised, but dividing the constriction proper, and restoring the urethra more nearly to its normal condition.

I do not hold that lateral strictures are the rule. In my own experience they are exceptional; yet, when they do exist, the more exact we are in the application of our science, the more credit we achieve for surgery in the better results for our patients.

Gouley,* a most experienced and careful observer, in describing the forms of stricture, writes: "A linear stricture

is due to the contraction of a narrow cicatricial band, which gives rise, by a duplication of the mucous membrane, to a thin diaphragmatic septum, with a central, often with an eccentric, orifice, and occasionally not involving the whole caliber of the canal, but forming a valvular crescentic fold, etc."

Van Buren and Keyes* define a stricture of the urethra, after Sir Charles Bell, as a loss of dilatability.

They say that all strictures may be ranged under three heads: linear, annular, and tortuous. A linear stricture is like what would be caused if a thread were tied around the canal; or it may consist of a thin membranous diaphragm, with its orifice in the center or on one side; or be a crescentic fold or free band, encircling the urethra entirely or partially in a transverse or oblique direction.

Sir Henry Thompson † writes that "organic stricture is a deposit of lymph round the canal of the urethra or some point which, not allowing the canal to open to the stream, narrows the current to that extent. . . . This lymph forms fibrous bands, which subsequently become somewhat rigid, while they more or less encircle the passage," etc.

Bumstead and Taylor,‡ in describing the form of stricture, declare that this necessarily varies with the amount and situation of the fibrous deposit which produces it. This may consist of a few fibers which encircle the whole or a part of the urethral circumference, etc.

From Agnew* I quote as follows: "In the first, or membranous variety, the band may be a single crescentic-shaped membranous fold, limited to one side of the canal," etc.

Gross || says it (the stricture) may embrace the entire circumference of the tube, or only a part of it, etc.

Hamilton ^ concludes, also, that "in form they are exceedingly varied, in certain cases being circular, surrounding the entire canal; in others, they are limited to one side only," etc.

Holmes ¶ says it occasionally happens that a fold of the mucous membrane obstructs the passage at one of its sides, only forming a crescentic septum, and so obstructing a segment of the caliber of the canal, etc. (Thompson.)

Otis † writes: "Persistent irritation of living tissue result in the aggregation of germinal cells and the development of connective-tissue corpuscles at the point of irritation. These, becoming organized in the submucous cellular tissue and the adjacent muscular structure of the corpus spongiosum, result in a more or less resilient band or bands, always completely surrounding the urethra," etc.

Of the famous authorities just quoted as to the existence of lateral strictures of the urethra, Professor Otis stands alone in his denial of such lesion, asserting that a "true stricture always, and of necessity, completely surrounds the urethra. That it may have its origin, its commencement, at a single point in the circumference, is quite evident; but, as

soon as the caliber of the urethra becomes lessened at any point, the resistance to the flow of urine which it necessarily occasions and the resulting interference with the harmonious muscular action produces an irritation in its whole circumference at the point of contraction, resulting, sooner or later, in an aggregation of fibro-plastic material not confined to a single point in its circumference, but around the entire canal."

Holding Dr. Otis in high esteem personally, and with great respect for the contributions which his industry and ingenuity have made to the literature and armamentarium of genito-urinary surgery, I can not accept his sweeping denial of the existence of lateral stricture of the urethra. The weight of authority is against him.

Even if every stricture were linear and lunar, all writers agree that the opening is rarely in the center. I hold, and the point I am making the endeavor to establish is this, that, when internal urethrotomy shall have been determined upon, the surgeon should, if possible, also determine the exact and minute character of the stricture; and if it be lateral, instead of cutting on the floor or roof of the canal, he should make the incision or incisions through the thickest part of the cicatricial diaphragm, no matter in which direction it requires the knife to be turned.

The danger of severe hemorrhage by cutting into the corpus spongiosum is not great, and, when proper care and skill are employed, it may be excluded. On strict anatomical grounds, as has been demonstrated by Professor Robert F. Weir, the roof of the urethra is the safer plane of incision, and in annular or long and tortuous strictures surrounding the entire urethra, where the cut must be deep, the knife should be turned to this plane.

As to the proper line of incision in internal urethrotomy, the difference of opinions is only second to the different results at which urethrologists have arrived in determining the part of the urethra which is the most frequent seat of stricture. Gouley prefers a clean longitudinal incision in the middle line of the urethral floor; sometimes a second one is done in the upper wall. Otis cuts on the floor from the external meatus to the end of the fossa navicularis, and on the roof from thence to the bulb.

Thompson and Agnew prefer the floor; Bumstead and Taylor, the upper median line; Van Buren and Keyes, both floor and roof; while Gross cuts the stricture on two, three, or more points of its circumference. Maisonneuve occasionally practiced one or more lateral incisions.

Personally, when the cutting operation must be done, I prefer to make the incision on the floor through the fossa, on the roof from the fossa to the bulb, and to treat all strictures of the membranous portion by continuous or gradual dilatation when this is possible, or by external section if patient efforts at dilatation have failed.

When, however, in the rarer cases, a lateral stricture can be made out, I cut the cicatricial band, no matter in which direction the plane of incision is indicated.

& Co., is pointed anteriorly, and shouldered on one side. On the tip of the handle is a little knob which corresponds to the side on which the shoulder projects. The opposite surface is smooth and continuous with the wire which forms the stem. The sizes correspond to the *bougies à boule* made on the American scale. It differs very slightly from the "half-olive" bougie of Leroy d'Etiolles (1845) figured in Gouley's work. The indicator on the handle-end of the stem renders its use more precise, while my instrument is only a flattened segment of the "half olive." To my knowledge, no other American writer mentions this instrument. When the indicator is insinuated through a lateral stricture, if it pass in and out with about the same degree of resistance, it is evident that the stricture band is not located on that arc of the urethral circumference over which the shoulder is passing. If, however, the instrument be entered again on the same plane, and then turned with the shoulder to the opposite side and withdrawn slowly, if it hang or catch, it is evident that upon this portion of the urethral circumference the contraction has occurred and the stricture is located. Repeating this manœuvre to confirm the diagnosis, the usual measurements are taken, and, with an Otis's or Banks's urethrotome, one or more cuts are made until resistance ceases and the introduction of the sound has been accomplished. I have performed this operation several times with satisfactory results. It is not one which will be often necessitated in the experience of the general practitioner, since the condition which might demand it will only occasionally exist; yet I claim that it is, both in the diagnosis and as an operative procedure, an addition to the exactness of our science.

THE RELATIONS OF A PHYSICIAN TO THE COMMONWEALTH.*

By E. C. HARWOOD, M. D.

(Continued from page 8.)

Medical Corporations.

The Medical Society of the State of New York and each of the county medical societies of this State are corporations created by the act passed April 10, 1813. The Legislature reserved the right to alter, modify, or repeal the provisions of this act at pleasure.

These corporations have, in general, the following rights:

1. To enjoy a given name.
2. To have and use a common seal.
3. To prescribe rules for the admission and expulsion of members and the election of officers.
4. To sue and be sued.
5. To purchase, hold, and sell property.
6. To impose fines, dues, and penalties on their members.

When a corporation is duly created, the law tacitly annexes to it the power to make by-laws or private statutes for its government and support, but the statute creating these corporations conferred upon them certain general

* Read before the Northwestern Medical and Surgical Society at its thirteenth annual meeting, December 19, 1883.

For purposes of diagnosis I use the lateral indicator represented in the figure. This instrument, made by Reynders

powers, such as to make by-laws and regulations for their government.

This power is conferred in general terms, and must be construed as an authority given for the purpose of enabling the corporation to accomplish the objects of its creation, and the power in its exercise is to be limited to such objects or purposes.

A by-law must not be at variance with the general law of the land. It must be reasonable, and adapted to the purposes of the corporation.

The by-laws of the medical societies must not only accord with the laws of the State, but must be adapted to the purposes of the corporations, as declared by the Legislature—that is, to contribute to the diffusion of true science, and particularly the knowledge of the healing art. These corporations can not make any regulation which is unreasonable, or opposed to public policy, or contrary to law. They may at their annual meeting make by-laws for the admission and expulsion of members, for the fees or dues to be paid by members, for an initiation or admission fee, to levy contributions upon members, for the standard and requisites for membership, but they can not prescribe a tariff of fees for medical services to be performed by their members, nor fix a minimum salary to be received by any member who should be appointed to a public office, because such a regulation is unreasonably restraining and oppressive, interferes with the private rights of members, and conflicts with the law and its policy in relation to contracts and trade.

The skill of a professional man is his capital in trade, and he has the undoubted right to employ it for a compensation satisfactory to himself, and by this means obtain a livelihood.

These societies must sue and be sued in the corporate names. They may contract such debts as are allowed by the statute creating them and by their by-laws, and, if judgment be obtained against them, execution may issue and their property be taken thereunder. They possess all the usual powers and privileges of ordinary corporations, and are liable in the same manner as general corporations.

Every physician must become a member of the medical society of the county in which he practices.

These societies are not simply voluntary associations of gentlemen for social purposes or mutual improvement under rules and regulations as adopted by themselves, but they are organized under the statute, and such organization is a corporation. Their powers are derived from the statutes, and their members have certain well-defined and valuable rights. Such rights are franchise, and the law will protect each member in the enjoyment thereof until they shall have been legally forfeited.

Every physician or surgeon, residing in the county in which the medical society to which he applies is situated, of temperate habits, good moral character, and legally authorized to practice physic or surgery in this State, is entitled to membership in such society.

Any physician or surgeon possessing these qualifications can not be refused admission for any cause unless it shall appear to be morally certain that, if he were admitted, the

society would have the immediate right of expulsion. This right must, however, be morally certain before membership can be refused.

As soon as a person becomes a member all the by-laws and regulations of the society are binding upon him, and any refraction of them is cause for expulsion.

It seems, also, that the code of ethics adopted by the various societies as part of their by-laws is binding on members; but the non-compliance with the requirements of the by-laws of a society, and with those of the code of ethics, is no ground for exclusion from a society of one not a member.

These societies have the right to expel a member, by a two-thirds vote of all the members present, for malpractice, gross ignorance, and immoral habits, and for such causes as may be provided by their by-laws. Expulsion is disfranchisement, and deprives the person expelled of all the rights and privileges of the society.

Any physician or surgeon refused admission or expelled from a county society may appeal to the Medical Society of the State for redress, or he may have the matter reviewed by the courts of this State.

Coroners' Inquests.

The office of coroner dates back to the Saxon period of English history. The duties and powers are both judicial and ministerial, but principally the former.

It has always been his peculiar duty to inquire into the causes of violent and sudden death, by a jury of proper persons, upon view of the dead body.

The ministerial office of the coroner is only as the sheriff's substitute in executing process.

The office in this country has lost most of the importance and dignity belonging to it in England, where its incumbent is one of the principal Crown officers.

According to the old English law in cases of persons dying, or found dead, the body must not be moved or touched before the arrival of the coroner, who shall be summoned instantly, and proceed without delay with the inquisition, which was to be held in the direct presence of the corpse till finished.

The practice in this country is considerably simplified, since it is only required that the proceedings of the coroner and a jury (six or more) shall be *super visum corporis*, and that a body, or a portion thereof, shall be produced.

Without the latter condition the coroner can not take a step toward investigating a crime. After a coroner and a jury have viewed the body, the inquest may go on at once where the corpse lies, or in a more convenient location, and it may be adjourned to any suitable time.

Unless the case is an unusual one, or the position and surroundings of the dead person tend to throw light on the manner of death, there is no objection to washing and laying out the body, and making the ordinary preliminary arrangements for burial. The classes of cases referred to the coroner are:

1. Deaths by criminal violence.
2. Deaths from casualties.
3. Deaths occurring suddenly in persons supposed to be healthy.

4. Deaths in which no physician had attended the deceased.

5. All suspicious or unusual deaths.

6. Deaths in prison.

7. Ante-mortem examination.

The last class is held upon persons who have been dangerously wounded. Should they be in a hopeless condition, their dying declarations are included in the ante-mortem inquisition.

It is important that physicians should be aware of the necessity of such declaration, and of what it should consist. For, to be effective and admitted as evidence in the courts, it must be made when the individual examined is *fully satisfied that he is about to die*, and that his dissolution is very near. Any hope of recovery, however slight, renders such a declaration inadmissible in evidence, and the question turns rather upon the state of mind at the time of making the declaration than upon the interval between it and death. The declaration is only admissible in evidence in a charge of homicide, and where the death of the deceased is the subject of the charge, and the circumstances of the death the subject of the declaration. Such declaration must be made before the coroner in the presence of a jury or other witnesses, and without the administration of an oath. The following is the amended law, passed in 1871, regulating coroner's inquests:

SECTION 1. Hereafter, when, in the city and county of New York, any person shall die from criminal violence or by a casualty, or suddenly when in apparent health, or when unattended by a physician, or in prison, or in any suspicious or unusual manner, the coroner shall subpoena a properly qualified physician, who shall view the body of such deceased person externally, or make an autopsy thereon, as may be required. The testimony of such physician and that of any other witnesses shall constitute an inquest.

Sec. 2. Should the coroner deem it necessary, he may call a jury to assist him in his investigation; or should any citizen demand that a jury be called, he shall proceed as directed by part four, title seven, article one of the Revised Statutes.

Sec. 3. It shall be the duty of any citizen, who may become aware of the death of a person who shall have died in the manner stated in section one of this act, to report such death forthwith to one of the coroners or to any police officer, and such police officer shall, without delay, notify the coroner of such death; and any person who shall willfully neglect or refuse to report such death to the coroner shall, upon conviction, be adjudged guilty of a misdemeanor, and shall be punished by imprisonment in the county prison not exceeding one year, or by a fine not exceeding five hundred dollars, or by both such fine and imprisonment.

Sec. 4. Any person, except the coroner, who shall willfully touch, remove, or disturb the clothing, or any article upon or near such body without an order from the coroner, shall, upon conviction, be adjudged guilty of a misdemeanor, and shall be punished by imprisonment in the county prison not exceeding one year, or by a fine not exceeding five hundred dollars, or by both such fine and imprisonment.

Sec. 5. Any citizen not over seventy years of age, and being at the time a resident of the county, may be summoned to serve as a juror upon a coroner's inquest; and any person who shall willfully neglect or refuse to serve as such juror when duly summoned shall, upon conviction, be adjudged guilty of a mis-

demeanor, and shall be punished by imprisonment in the county prison not exceeding one year, or by a fine not exceeding five hundred dollars, or by both such fine and imprisonment.

The fees allowed a physician for making external examinations are three dollars; for making autopsy, ten dollars, such sums to be a county charge.

Any citizen under seventy years of age may be summoned to serve as a juror, and physicians, if summoned, though it is not usual to require them, must serve.

The summons, or subpoena, to a physician to attend and make an examination and give evidence must be served personally, and no fees are provided, it being in the nature of, and subject to, the same rules as criminal cases. This subpoena may issue to any regular physician in actual practice in or near the place where the death happened.

The cases in which inquests must be held are only those mentioned in the first section of the foregoing act.

The words "suspicious or unusual manner" are very indefinite, and leave many cases open to the discretion of the coroner, who has the authority to order an inquest in any case when death has resulted out of the ordinary course.

By an act passed in 1874, a coroner was empowered, when he deemed it necessary, to employ not more than two competent surgeons to make post-mortem examinations and dissections, and to testify to the same, the compensation therefor to be a county charge.

A medical man should remember that, in giving evidence at an inquest, the coroner is in all cases likely to commit the accused person, and that his evidence may involve the accused in a charge of manslaughter or murder, or may cause him to be imprisoned for months previous to trial.

All opinions, therefore, should be well weighed, and only given after a careful inspection of the body. Such inspection is absolutely necessary, and should be made with the greatest care; and after it the physician will be called upon for his opinion, which, if not well considered and formed upon sufficient evidence or data, may involve him in an unpleasant responsibility.

The physician is entitled not only to a careful inspection of the body, but also to any information in relation to the habits of the deceased, and the circumstances under which death resulted. Reports are frequently made, and these, with the deposition of the physician, are filed, and counsel for the people and for the accused have access thereto.

If the accused is indicted, the physician may be called upon to testify upon the trial, and his evidence as given upon the trial will be compared, word for word, with the reports; and if there is any material difference between them, it may furnish materials for cross-examination to the counsel for the prisoner. These reports, therefore, should be most carefully drawn, and contain only such facts and circumstances as are connected with the subject of inquiry, and which had actually fallen under the observation of the physician.

All exaggerated language and the too free use of technical terms should be avoided. The facts should be stated with particularity, and, if any comments be necessary, they

should be separately stated, and care should be taken to avoid anything like a dissertation upon the subject.

All hearsay statements must be excluded.

In a report of an analysis of a case of suspected poisoning it is not necessary that all the details of the analysis should be set forth at length. A general statement of the results, the effect of certain tests and processes which may have been used, will be sufficient.

Malpractice.

Every medical practitioner who, by a culpable want of attention and care, or by the absence of a competent degree of skill and knowledge, causes injury to a patient, is liable to a civil action for damages even where the patient neither employed him nor was to pay him, unless such injury be the immediate result of intervening negligence on the part of the patient himself, or unless such patient has, by his own carelessness, directly conducted to such injury.

Every person who publicly announces himself to be a physician is presumed to have the ordinary qualifications for the practice of medicine; and, though he does not undertake to perform a cure nor to use the highest possible degree of skill, he undertakes to employ a fair, reasonable, and competent degree of skill in the care and treatment of the patient.

The law implies an undertaking on the part of every medical practitioner to use an ordinary degree of care and skill in his practice, and will hold him responsible for gross negligence or unskillfulness.

The negligence or ignorance must be *gross*, and by these terms is meant carelessness, want of due diligence, harsh and unsentimental treatment, unwarrantable experiments, and the like.

The administering of improper medicines, or over-doses of medicines of notoriously dangerous character, or pursuing a course of treatment which has been held by the profession at large to be improper, are all actionable where ordinary care and skill have not been used. But, if the patient, by his own acts, has directly contributed to the results, no action will lie. This is called contributory negligence, and the general doctrine is that, although there may have been negligence on the part of the patient, yet, unless he might by the exercise of ordinary care have avoided the consequences of the physician's negligence, he is entitled to recover; but, if by ordinary care he might have avoided them, he is the author of his own wrong, and can not recover. Ordinary care and skill are the usual or necessary care in attending, or the usual mode of treatment of the particular case or disease.

In case of malpractice, the principal evidence is necessarily that of experts, and, from the variety of schools of medicine and modes of treatment, it is frequently the case that as many witnesses of respectability and reputation in the community are produced on the part of the plaintiff as on that of the defendant. The parties to the suit are examined orally, and their statements of the treatment pursued and the result of the treatment are generally directly opposite.

In cases of injury to children, oral examination is gen-

erally useless, and the physician labors under great disadvantages. In such cases it is easy to perceive that a personal examination of the alleged injury might set at rest all doubt on the question, and relieve the physician of the charge of malpractice. But until recently no personal examination was permitted, it being considered a personal trespass. There is, however, a case where an action was brought for an alleged injury to a child seven years of age, when the Court, upon an application of the defendant, allowed a personal examination, and appointed several medical men as a commission for such purpose. This case, however, was not appealed, and has not been passed upon by the higher courts, and is the only one on record in which such an examination was allowed.

A medical man who is guilty of gross negligence, or evinces a gross want of knowledge of his profession, is criminally responsible for the consequences, but is not liable to a criminal investigation for every slip.

It must be something substantial. The distinction between actionable and criminal negligence can not be defined except so far as to say that to constitute the latter there must be such a degree of complete negligence as the law means by the word "felonious."

Whenever death ensues as the alleged consequence of malpractice, it then becomes necessary to inquire into the conduct of the physician, so as to determine how far his want of skill or negligence has conspired to produce it.

The question of intention enters largely into cases of this character, and is to be deduced from the accompanying facts and circumstances.

The remedies prescribed and the treatment pursued are to be investigated, and, as every physician is presumed to know the consequences of the particular medicines administered and the treatment pursued, as falling within the line of his calling and forming part of the skill belonging to it, the intention of his act is therefrom fairly to be deduced. Hence, if a physician administers poison in poisonous doses, or pursues a course of treatment which the experience of the profession has condemned as unsafe, he can not escape the presumption of wantonly trifling with life or health.

Confidential Communications.

Formerly communications between attorney and client were alone considered privileged. In this State, however, contrary to the general rule, this privilege has been extended to the profession of medicine, and, by II. Revised Statutes, p. 406, information disclosed to a physician while attending a patient in his professional capacity, which information was necessary to enable the physician to prescribe for his patient, is declared to be a confidential communication which the physician is not allowed to divulge without the express consent of the patient, for this is the privilege of the patient, not of the physician.

The theory of the law is that the welfare of society must be assured, and, as in the case of attorney and client, it is desired to protect the client and make the pursuit of justice more certain and easier of attainment. So, in regard to the profession of medicine, it refrains from placing any obstacle in the way of a full and frank confidence between

physician and patient, and therefore makes the physician incompetent to testify regarding all information of a confidential character which he has acquired in the practice of his profession. Thus, if a physician were called upon to prescribe for a patient, and the patient disclosed the fact of some organic defect, the physician could not testify regarding such defect. The same rule applies to cases where the physician, acting in his professional capacity, had discovered the defect without any declaration of the patient, as in the case of a family physician who had been accustomed to attend the patient from childhood, and had, through this means, become perfectly acquainted with his constitution and habits. The privilege, however, does not extend to extraneous or impertinent communications, nor to information imparted to a physician in the character of a friend and not as a physician.

Where communications come under the following heads they are not deemed confidential or privileged:

1. When the communication was made before the physician was employed as such.
2. After the physician's employment has ceased.
3. When the physician was consulted because he was a physician, yet he refused to act as such, and was therefore only applied to as a friend.
4. Where a fact merely took place in the presence of a physician.
5. When the matter communicated was not in its nature private, and could in no sense be termed the subject of a confidential communication.

A physician, when called upon to testify as to anything communicated to him in his professional capacity, must plead his privilege.

The privilege is that of the patient, and not of the physician, and can only be waived by the express consent of the patient.

The privilege does not survive the decease of the patient, as after his death there is no person entitled to assert it. Hence it has been held that the statute has no application where a physician is called as a witness to testify touching the capacity of his patient to make a will upon an application for probate of the will.

Actions for Defamation.

Actions of this character come under the terms of libel and slander. Libel, or written defamation, applies to such words as are written, and the law regards such an offense as more heinous than that of slander, which is oral defamation, and consists in words spoken. Such words are actionable *per se*, or by the effect and impression created by them.

Words actionable *per se* are such as are sufficient of themselves to cause a man injury in his business or profession, or to tend to bring disgrace upon him and cause him to be shunned and avoided by others.

Thus, if a physician were to announce generally that a certain person was affected with a contagious disease, an action would lie against him, because it would exclude the person from intercourse with other men.

If a physician were to declare that a person's mind was in an unsound condition, and was giving way, an action

would lie, provided it could be shown that damages had resulted to the person on account of such defamation. Such damage is called special damage, and must be proved.

All words imputing misconduct, or gross ignorance, or incapacity to professional men in the discharge of their professional duties, are actionable *per se*, without proof of any special damage. Such as words imputing to a practicing physician that he is a quack, or a mountebank, or that he has killed a patient through ignorance of the first principles of his profession; or words imputing to a surgeon or accoucheur the want of proper qualifications for his profession or business, or the want of skill, or of any professional requisite; or that his character is so bad among professional men that they will not meet him in consultation; or that he had seduced or committed adultery with one of his patients. In these cases it is not necessary that the loss or damage should have actually arisen at the time. In all other cases the damages must be proved, and must have actually occurred, and be the natural and direct consequence of the wrongful act, and not too remote.

Partners may sue jointly and recover damages for injury sustained in their joint business.

An action for libel and slander must be brought within two years after the cause of action has arisen.

Experts.

In general—as a principle—the law only permits witnesses to testify regarding facts coming within their own personal knowledge; yet there are exceptional cases in which it is found expedient to admit as evidence the opinion of the witness, and not what he actually saw or heard, but what he believes to be true, judging from past experience and information.

Under this head is classed the testimony of medical men who, in the language of the law, are known as “experts”—that is, men instructed by experience, and professionally acquainted with the subject-matter of the discussion.

In order that such testimony may be introduced, it must appear that the fact to be proved requires more than the ordinary knowledge which the average man possesses—that is, the fact must be of such a nature that an inexperienced person would be liable to error; and that, in order to form a correct judgment, some preparation and study must have been necessary.

Medical experts are generally entire strangers to the party regarding whom the controversy is instituted, and are only permitted to testify as to the facts already proved by other testimony. They can only say what, in their judgment, would be the result of certain facts submitted to their consideration, and can not give an opinion as to the general merits of the case, nor as to questions with which a jury may be supposed to be equally well acquainted.

A hypothetical case, introducing the circumstances of the particular controversy, is generally put, and they are asked what, in their judgment, would be the condition of a person under such circumstances, or what would be the effect of such treatment. All that is required to entitle one to give evidence as a medical expert is that he has been

educated as a physician, and has had some experience in his profession.

One may testify as an expert although he is not engaged in the practice of his profession.

The Court at the trial decides whether a witness offered as an expert has the necessary qualifications, and, if his testimony is admitted, it is for the jury or tribunal to determine the weight due to such testimony in each particular instance.

In almost all cases where a medical expert is called in he is required to pass an opinion upon the professional skill or practice of another professional man. In such cases it is the duty of a witness, in answering questions put to him by counsel, to state his opinion, and the grounds upon which it is based, clearly and distinctly; but he is not bound to be forward in pointing out and suggesting defects, and should not endeavor to lower another practitioner in the opinion of the public. He should conceal nothing which is relevant to the elucidation of the case at issue, but he should volunteer nothing.

Care should be taken in giving testimony to be prepared to answer any question that may be put in regard to anatomy, or which has any bearing on or connection with the case.

Great latitude is allowed counsel on cross-examination, and an expert should be prepared to answer all questions, even though they may seem impertinent, in regard to the length of time he has studied and practiced medicine, his habits, associations, and particular practice and advantages.

These questions are generally asked, and go to show the weight due to the testimony given by the expert.

A medical man may be called as an expert in any case requiring medical testimony, and, if, upon being personally served with subpoena, his fees in a civil action are paid, he is bound to obey the subpoena.

The fees in civil cases on services of subpoena are fifty cents, and, if out of the city or town, mileage is allowed.

In criminal cases no fees need be paid, though, if the distance is great, the physician is entitled to a small sum for mileage.

There is no provision for the payment of medical men when called upon to testify as experts. Some compensation should be provided by statute, as it is a great hardship to compel a physician in active practice to leave his business and attend at court, sometimes for days, to his great damage pecuniarily.

If, however, a medical man is employed to examine a case as an expert, and to give his testimony from such examination, if no special agreement is made as to the amount, he may sue for and recover such an amount as his services may be reasonably worth, and this may be done even if the physician has not been called upon to give his evidence after making such an examination. In such cases it is always best to have the amount of compensation agreed upon by the parties, as it may be very difficult to prove that the examination made by the physicians was worth the amount charged.

(To be concluded.)

SCARLET FEVER AND MEASLES

IN DOGS AND CATS.

By JOHN C. PETERS, M. D.,

NEW YORK.

COPELAND, Ziemssen, and many other writers allude to scarlet fever in dogs, but in such a perfunctory way that nobody pays much attention to it. Some months ago I attended a case of scarlet fever in a young lady who had a pet pug dog. It so happened that I had seen this dog several times when well; finally it sickened, and seemed to have what is called "distemper," to which all young dogs are subject, like children to scarlet fever and measles. Of course, I paid little or no attention to it, but recollect that it appeared to have a feverish cold, with sore eyes and throat, refused its food, and rapidly fell away in condition. It was sent to a dog doctor, and soon after its young mistress had a very decided outbreak of scarlet fever, about which there could not be the slightest doubt. Her eyes were affected more than is usual in scarlet fever, and the mother repeatedly called my attention to the similarity of some of the symptoms of the dog-distemper to those of her daughter. I warded off these gentle attempts to establish a connection between the disorder of the dog and that of its young mistress. Many months after, when I became interested in the possible occurrence of scarlet fever in horses, the mother again stated her belief, which she had never abandoned, that the dog had had the same disease as her daughter, and that the canine disorder, as I well knew, had the precedence in point of time. Subsequently I learned that the dog had been taken along several times by a waiter man when inquiries were made about another young lady sick with scarlet fever.

This case, standing alone, would, of course, form a very slender basis for anything else than to suggest that sick dogs should be examined more carefully by doctors in the future. Soon after I heard that Dr. Alexander Hadden knew something about scarlet fever in cats, and, after several conversations with him, persuaded him to write out his opinions, and, on December 5th ult., received the following letter:

"DEAR DOCTOR: About fifteen years ago my attention was called to scarlatina in animals by an article published by the well-known Dr. Snow, of London, in a medical journal which I have lost, and the name of which I have forgotten. The purport of his paper was that cats were often the carriers of scarlet fever to families; that they were subject to this disease, and often communicated it to their kind and also to human beings. He also stated that they died of this malady, and then presented the common post-mortem appearances of unmistakable scarlet fever, especially in the skin and kidneys. His statements were so positive that I bore them in mind, and, when other well-known sources of the contagion were not present in the cases I met with in practice, I inquired about the condition of these common house pets. The first cases which fastened my attention to this point still more were three children in one family all attacked with scarlet fever about the same time. They had not been exposed to scarlet fever in any known way, for they had not been out of the house for several weeks, as they were snow-bound in the country, and the weather was very cold.

THE RHODE ISLAND HOSPITAL.—Dr. Godding and Dr. Mann, of Providence, have lately been appointed to positions on the staff.

There was no scarlet fever in the neighborhood, and few or no visitors had come to the house. I asked if there were any sick cats in the family, and was told that the house cat had been ailing for a week with sore throat and eyes. The animal was sought for but could not be found, although it had been seen lying beside the stove in the morning. It never returned, and therefore I was left with incomplete evidence. The next case which presented a like suspicious history was in a boy aged ten years, who, about four days before I was called, had been caring for a sick kitten which he had found in the street, and which died on the following day. The lad had not been exposed to the contagion from any human being, as far as could be ascertained; there was none in the neighborhood where he lived. His attack was well marked and very virulent, so that he died on the third day. In the following week his little sister was taken with the same disease, scarlet fever, but had it less severely, and recovered. In this case, also, I was deprived of the opportunity of obtaining positive evidence for or against the suspected origin of the contagion.

"On several occasions I tried to produce scarlet fever in kittens by exposing them to the disease, but obtained no absolutely satisfactory results. The plan I pursued was to place kittens about six weeks old in bed with children suffering with scarlet fever, and allow them to remain there parts of several days. Some of these animals became sick with catarrhal affections of the eyes and throat, but none exhibited the rash upon the skin, or characteristic glandular inflammation of the neck, or marked renal conditions."

I also persuaded Dr. Erskine S. Bates to write out his experience, as follows:

"DEAR DOCTOR: In looking over my case-book, I find the following notes, which may be of interest to you and others. They are necessarily meager, as the subject did not at that time possess the interest it will now: On March 6, 1877, I was called to attend Maggie W., aged seven. Her mother stated that the child had been very sick all night, and she was afraid she had caught some disease from a strange kitten which she had found in the hall some days previous. The kitten was sick when found, and the child had been nursing it ever since. I did not attach much importance to the mother's fears, but found that my little patient had scarlatina anginosa, and so informed the mother. The next day the mother again referred to the case of the sick kitten, and told me that the family cat was now also sick, very much like the kitten, and asked me to examine both animals. I did so very skeptically, and found both cats with high fever, scarlatinous sore throats in different stages, and some discharge from the nose; they were both very sick. As the child was quite ill, little attention was given to the felines beyond watching them casually from day to day. The family cat died on the sixth day; the kitten recovered, as did the little girl. Other cases of scarlet fever subsequently developed in the same house, but I am not sure whether any other of the felidæ contracted the disease.

"Two years after, I was called to see a young man, aged twenty-eight, who had recently married and set up housekeeping in a tenement building on Avenue A. His family consisted of his wife and a pet terrier dog. The house had a bad reputation on the score of healthfulness; family after family would move in, contract some form of scarlatina, lose one or more children, and then move out. The newly made family man had been domiciled there scarcely a week when he was attacked with scarlatina maligna, and died in forty-eight hours. The pet dog persisted in lying on the bed, as near the head of his master as he could get, all through his owner's illness; and, on the same day that his master died, was taken with convulsions, sore

throat, rapid swelling of the glands of the neck, high fever, suppression of urine, etc., death closing the scene thirty-six hours after the convulsions which ushered in the attack. The train of symptoms manifested by the animal was so similar to that of his master that the mourning friends commented on the matter. I had no doubt then, as I have none now, that the dog died of scarlatina maligna. Subsequently the house was thoroughly disinfected and renovated, and I am not aware that any peculiar fatality has since attended its occupants."

Even if the animals are not sick, they may convey the poison in their fur, as was suggested by Dr. Snow, whose opinions as the originator of the whole doctrine of water-contamination in the conveyance of cholera, typhoid fever, and other diseases are entitled to the highest respect. Dr. Janeway has reported a case in which diphtheria was conveyed from New York to Florida in the fur of a toy rabbit. Dr. Williams, President of the Royal College of Veterinary Surgeons, and Principal and Professor of Veterinary Medicine at the Veterinary College, Edinburgh, says, p. 253 of his "Principles and Practice of Veterinary Medicine," republished by William Wood & Co.: "I can compare dog-distemper to no human disease except measles, and the points of analogy are very great. In both diseases catarrhal symptoms are manifested; they are infectious; they generally occur but once in a life-time; they chiefly affect the young; in almost all cases of distemper there is some *cutaneous eruption or rash* and desquamation of the cuticle: catarrhal ophthalmia, bronchial and pulmonary inflammation, and dysentery are complications of both diseases," etc.

Book Notices.

Leçons sur les maladies mentales. Par B. BALL, Professeur à la Faculté de Médecine de Paris. Paris: Asselin et cie, 1880-1883. Pp. x-884.

THIS work comprises a series of lectures delivered by Dr. Ball at the Faculté de Médecine in 1875 and 1876. The author's intentions are to place before the profession the most indispensable ideas of mental pathology in a comprehensive and concise form.

Dr. Ball's great experience has enabled him to carry out his intentions in a very successful manner, and to produce a work not only of great merit, but one which proves the author to be one of the most advanced alienists of the day. The opening chapters contain the history of mental physiology from primitive periods to the present date, advance the theories of Pinel and Esquirol, and introduce a rather elementary form of classification. Further on, a tabulated classification is presented which, while it completely covers the subject, is singularly free from unnecessary and confusing divisions.

In defining insanity, a question of the greatest interest to all alienists, Dr. Ball's ideas would have been received with marked consideration and attention, but, in adhering to Esquirol's definition that "insanity is a disease of the brain, ordinarily chronic, without fever, and characterized by disorders of sensibility, of the intelligence and of the will," he not only fails to add anything new to the subject, but retains an old definition which, though it may have been, at the time it was originated, consistent with the ideas of psychiatry then current, must now, in our present state of knowledge, be regarded as inefficient and

erroneous. Dr. Ball's definition of an insane person is concise and to the point. "An insane person is one who, in consequence of profound disorder of the intellectual faculties, has lost his moral liberty more or less completely, and consequently has ceased to be responsible to society for his actions." This corresponds very closely to the legal definition.

In speaking of the treatment, Dr. Ball begins with the statement that he considers insanity to be an essentially curable disease, especially so in the initial period, and deplores that patients are not treated at that time by competent alienists. He considers isolation, preferably in an asylum, essential, especially in cases of delirium and mania. Hydropathy, in the form of baths continued for hours and even days, is recommended, together with the usual list of internal remedies.

The chapters on the causes, symptoms, and pathology, although containing nothing new, are well written and comprehensible. This is especially true of the section on general paralysis, to which several lectures are devoted.

Taking the book as a whole, it has certainly achieved its purpose.

Types of Insanity; an Illustrated Guide in the Physical Diagnosis of Mental Disease. By ALLAN McLANE HAMILTON, M. D., one of the consulting physicians to the insane asylums of New York City, etc. New York: William Wood & Co., 1883. 4to, pp. 36; ten plates. [Portfolio cover.]

We regard this work as an exceedingly creditable production. Subordinating generalization to the task actually in hand—that of portraying the striking features displayed by the subjects of the typical forms of mental disease—Dr. Hamilton has furnished us with a series of delineations far more available for purposes of diagnosis than the most elaborate and labored descriptions. There is, to be sure, little in these plates that may be called admirable from an artistic point of view; they are rugged and bold, and withal most graphic—and it is precisely those qualities that are needed for the purpose.

Vulnableness as the drawings are, it would be a grave mistake so to take it for granted that they constitute all that is of worth in the book. The text is an indispensable guide to their proper interpretation. Moreover, it includes a very useful summary of the laws governing the commitment of lunatics in the various States. It also contains judicious suggestions to the practitioner in regard to methods of examining persons supposed to be insane, and as to the conclusions to be drawn from the facts brought out in such examinations.

A Treatise on the Diseases of the Nervous System. By JAMES ROSS, M. D., LL. D., Fellow of the Royal College of Physicians, London, etc. Illustrated with Lithographs, Photographs, and Three Hundred and Thirty Woodcuts. Second Edition, Revised and Enlarged. New York: William Wood & Co., 1883. Two vols. Pp. xxi, 1,023; ix, 1,047.

In no department of medicine is there a demand for accurate and profound work to such a degree as in that of diseases of the nervous system. It proposes for explanation not only anatomical lesions and perverted functions, but a series of enigmas in regard to human action which have come thither as to "a court of last resort," and have been the occasion of the most patient and praiseworthy investigation. From neurology one passes easily to psychiatry, and this is kindred to psychology; hence the value of the former as a factor in completing the knowledge of the human intellect. To publish to the world, therefore, a treatise upon this subject is a brave undertaking, whether for the purpose of setting forth one's own opinions and investigations, or to serve as a compendium or collation of the works of

others. Both varieties are useful. The treatise under consideration is essentially of the latter class.

There are few medical books which show in their arrangement better evidence of a logically constructed plan. Nothing is assumed; the work begins with the primitive germ, and the subject is unfolded in the order of nature. It is interesting reading, because it is so clear. The style is that of a history or an essay, and not a mere clinical digest. It is an encyclopædia of facts and of references to the literature of France, Germany, England, and America. For a work of its kind, it is too voluminous. The parts that could best be spared are the numerous chapters on the anatomy and physiology of the various divisions. This work is well done, and is serviceable, especially as a means of reference; but there are works which are particularly devoted to these subjects, while this, to judge from its title, is devoted to diseases of the nervous system.

The author advances no new theories of his own, but his work may be considered a mirror of the most authentic literature in this department. Dr. Johnson said of Burton's "Anatomy of Melancholy" that it was the only book that would get him out of bed an hour earlier than usual in the morning. In point of entertaining character, profit, and the great amount of work exhibited in its preparation, we can see a resemblance to this book which we have had under consideration.

An Ethical Symposium: being a Series of Papers concerning Medical Ethics and Etiquette from the Liberal Standpoint. By ALFRED C. POST, WILLIAM S. ELY, S. OAKLEY VAN DER POEL, LEWIS S. PILCHER, THOMAS HUN, WILLIAM C. WEX, JOHN ORDONAU, DANIEL B. ST. JOHN ROOSA, CORNELIUS R. AGNEW, ABRAHAM JACOBI, and H. R. HOPKINS. With an Appendix. New York: G. P. Putnam's Sons, 1883. Pp. ix-213. [Price, \$1.25.]

This collection of essays on questions connected with the controversy that has now been carried on in the profession for the past two years includes contributions by men who are known as well for their general unwillingness to enter into controversial discussion as for their prominence in the legitimate work of medicine. It must be granted, therefore, that what they have here written is fairly entitled to be pondered along with what has been set forth on the same questions by Dr. Flint, Sr., and Dr. Piffard.

Viewed as a campaign document, the book is undeniably strong, but it may be questioned if the physicians of the State of New York, for whom, we take it, it is specially intended, have not long since made up their minds on the main question. There may be some of them, however, who are still unsettled, as well they may be, in view of the many false issues that have been raised; and for them the contents of this volume ought to put the ideas of the new-code party in an intelligible light.

BOOKS AND PAMPHLETS RECEIVED.

The International Encyclopedia of Surgery. A Systematic Treatise on the Theory and Practice of Surgery, by Authors of Various Nations. Edited by John Ashhurst, Jr., M. D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated with Chromo-lithographs and Woodcuts. In Six Volumes. Vol. IV. New York: William Wood & Co., 1884. Pp. xxiii-987.

Veterinary Medicine and Surgery in Diseases and Injuries of the Horse. Compiled from Standard and Modern Authorities, and edited by F. O. Kirby. Illustrated by Four Colored Plates and One Hundred and Sixty-eight Wood Engravings. New York: William Wood & Co., 1883. Pp. 332. [Wood's Library of Standard Medical Authors.]

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JAN. 19, 1884.

THE EMERSLEBEN OUTBREAK OF TRICHINIASIS.

IN view of the part lately taken by M. Paul Bert in affording scientific aid and comfort to those Frenchmen who are interested in keeping American pork out of France, it becomes a matter of some moment to ascertain the opinions of other scientific men on the Continent as to the reality of the dangers alleged to lurk in the flesh of the American hog. Some light is thrown upon the matter by M. Brouardel's account of an investigation of the recent outbreak of trichiniasis at Emersleben, in Saxony, conducted by himself and M. Grancher. Briefly stated, M. Brouardel's story, as given at a recent meeting of the Paris Academy of Medicine, and published in the "Gazette hebdomadaire de médecine et de chirurgie," is as follows:

The outbreak took its origin from a trichinous hog which was the offspring of an English boar and a native sow. This hog, which had been kept in a stable, was killed on the 12th of September. The butcher gave a slice of the carcass to two of his neighbors, who ate it raw the next day. Both of them fell sick on the 16th, and died a month later. The remainder of the meat was minced by the butcher, mixed with other meat, and was sold from the 13th until the 19th of September. All who made use of this mixture, except five persons who took it slightly cooked, used it perfectly raw, spread on bread, after the German fashion, and soon there were two hundred and fifty persons sick with the disease, of whom forty-two died. In the neighboring villages, sausages sold by the same butcher gave rise to a hundred and twenty-six cases, of which eleven were fatal. At first the true nature of the trouble was not suspected, but subsequent facts left no room for doubt on this point. M. Brouardel and M. Grancher made two post-mortem examinations, and found trichinæ in abundance in all the muscles in which they are usually to be found. It is considered worthy of note that the severest cases were those of persons who ate the meat soonest after the animal was killed; its morbid effect seemed to diminish steadily with the lapse of time. The woman who cooked the meat for the family of five persons who escaped infection was herself affected, having eaten some of the mixture before cooking it.

M. Brouardel doubts the efficiency of an inspection of pork under ordinary circumstances; it is tedious, difficult, and unsatisfactory, he remarks, unless the examiner has access to the whole carcass. Moreover, it is unnecessary, since every one has it in his own power to guard against infection by simply cooking the meat. Is it well, then, he asks, to renew the prohibition of the importation of American salted pork? Virchow is quoted as having stated to M. Brouardel and M. Grancher

that never to his knowledge had it been demonstrated scientifically that the use of American pork had given rise to a single case of trichiniasis in the human subject in Germany, although it was eaten raw.

When we consider that M. Brouardel's remarks were a *résumé* of his official report to the minister of commerce, their force becomes doubly obvious. It is plain that, if any inspection of hogs is to be relied on to allay the fears of those who really believe the American animal to be so dangerous as M. Paul Bert would have them think, that inspection must, in view of the difficulties to which M. Brouardel calls attention as inseparable from operations with the marketable product, be carried on at the place of slaughter, rather than at foreign ports of entry. As our Government seems disposed to provide for such inspection, it remains only a question whether our European friends are willing to trust to American inspectors.

THE MECHANISM OF RUNNING.

AN article in the "Gazette hebdomadaire de médecine et de chirurgie" for November 9, 1883, describes M. Marey's ingenious application of the process known as instantaneous photography to the delineation of bodily movements in general, but especially those involved in the act of running. As a distinct image is produced on a sensitive surface of gelatinized bromide of silver by an impression lasting only $\frac{1}{250}$ of a second, the apparatus referred to is capable of furnishing no fewer than forty well-defined representations of a human subject while the latter is passing as rapidly as possible over the space covered by a single step. These successive images, being taken at equal intervals of time, not only show the relative positions of the body and limbs at each corresponding instant, but also render it possible to deduce a law of movement applicable to any given point of the person depicted. This law being ascertained, the nature of the forces concerned can also be determined. Thus far, however, these possibilities are hardly more than theoretical, the experimental data obtained by M. Marey not having yet been subjected by him to the laborious scrutiny required for a complete solution of the problem.

The principal point to be considered in this inquiry was that which regarded the intensity and direction of the forces brought into play by the contact of the feet with the ground. M. Marey, assisted by two of his colleagues, devised a method of estimating these forces by means of plates fitted to the soles of the subject's feet, and resting upon India-rubber tubes. These tubes are closed at one end, and at the other open into a reservoir which is connected with a registering drum. The downward pressure exercised upon the tubes in walking or running forces the contained air into the drum, thus causing a lever which is moved by the drum-membrane to leave a trace on a revolving cylinder. In this way the equivalent of the successive vertical pressures is obtained in kilogrammes. That of the horizontal impulses imparted to the feet is arrived at by causing the dynamometer, when moving forward, to roll upon small balls in connection with which a registering apparatus is employed similar to that just described. As yet, merely tenta-

tive experiments have been made with this instrument, and only a partial light has been shed upon the physiological processes involved in human locomotion. Extreme care is called for in judging of the indications afforded by such methods of registration when applied to movements that are at all rapid. Means of exact verification unquestionably exist, and it is also possible to conduct the experiments under conditions excluding all possibility of error. The results hitherto attained are, however, insufficient to settle finally a question which has been raised in regard to the mode in which running is accomplished. This question may be stated as follows: Running is very possibly performed in some cases (especially of those persons who have never really learned to run) by a series of leaps. On the other hand, it is also possible that, as M. Marey supposes, the feet, in executing this movement, may spring aloft without any forcible rebound—without impulse imparted by the ground—but merely through a rapid flexion of the limb. That this is the real method has not yet been proved experimentally. The matter can only be decided by a thorough prosecution of M. Marey's investigations.

MINOR PARAGRAPHS.

A NEW MEDICAL SOCIETY IN NEW YORK.

A MEDICAL society has lately been organized in New York, entitled the New York County Medical Association, of which Dr. William Detmold is president, and Dr. E. A. Judson secretary. The new organization includes among its members several of the gentlemen who have taken a prominent part in opposing the recent action of the Medical Society of the County of New York and the Academy of Medicine on matters connected with the ethical controversy, and it is generally understood that the new society was organized as a sort of protest against that action. Be that as it may, it is pleasant to be able to record that the president, in the course of his remarks at the first meeting, spoke in terms that have been interpreted as conciliatory. On the occasion referred to, last Monday evening, Dr. Austin Flint, Sr., read an exceedingly valuable paper on the relations of the bacillus of Koch to tuberculosis, and Dr. William H. Welch presented an interesting specimen of echinococcus of the liver.

THE CONTAGIOUS PLEURO-PNEUMONIA OF CATTLE.

In the matter of this plague, as well as in that of the interests of our pork trade, Congress seems to be awaking to a just sense of the necessity of taking some decided action. The foreign origin of the disease is properly dwelt upon, and there is little doubt that quarantine measures adequate to the prevention of further importation will be provided for. But, in addition to guarding against fresh sources of infection in the future, we have to deal with those already established in various parts of the country. To this end the liberal use of money is necessary, and the temper of Congress seems to be to grant the funds required. Notice has been given in the House that a bill will be introduced appropriating \$10,000,000 for the purpose of suppressing contagious diseases among cattle, the amount to be distributed according to the different State and territorial representations in Congress, but providing that each State and Territory must itself contribute a sum equal to what it receives out of the appropriation. On the authority of Professor Law, of the Cattle Commission of the Treasury Department, it is

expected that, with sufficient appropriations, the disease can unquestionably be stamped out within a year.

The measures thus far alluded to seem to have had their origin among members of Congress. Others are to be asked for, it is reported, by those interested specially in the cattle trade. A deputation representing a recent meeting of these gentlemen in Chicago has been in conference with the Department of Agriculture, as a result of which action a memorial is to be addressed to Congress asking for legislation making the shipment of cattle known to be diseased a penal offense, establishing a Cattle Bureau in the Department of Agriculture, and giving the Commissioner of Agriculture increased powers for action in eradicating the contagious diseases of cattle.

THE MORAL EFFECT OF BOTANICAL STUDY.

Is there anything essentially infuriating to the ordinary medical student about the study of botany, or does he simply single out that gentle science as the most available field in which to display his resentment at all amplifications of the curriculum? Not many years ago a professor of botany was actually compelled to leave the faculty of the University of Vienna and return to Berlin, all because his life was made miserable by the students. He had had the misfortune to come to the chair as the successor of an amiable but somewhat lax old gentleman. Unlike the latter, he insisted that the students should really learn botany, and personal violence was his reward. A like story now comes to us from Canada. It seems that some of the medical students at McGill University, in Montreal, are said to have maltreated their professor of botany lately, because he had raised the standard of his examinations.

YELLOW FEVER IN NEW YORK.

Last Sunday a man died of yellow fever in Perry Street. He was a resident of New York, who had recently visited Havana, where he remained eighteen days and then returned home, arriving in New York on the 7th inst. The first manifestation of the disease seems to have taken place on the day after his arrival. It is comforting to learn that the Board of Health does not consider that there is any danger of the disease spreading. None of the facts in the case point to there having been any warrant for the detention of either the man or the ship at the quarantine station, but the incident ought certainly to be taken as showing the utter folly of laxity in our quarantine system.

GLUCOSE AS AN ARTICLE OF FOOD.

THE popular outcry against glucose, senseless in so far as it is founded on the notion of its injurious action upon the system when taken into the stomach, but quite justified as a protest against the mania for adulteration, is likely to be somewhat quieted by a report upon the subject lately made to the Commissioner of Internal Revenue by a committee of the National Academy of Sciences, consisting of George A. Barker, William H. Brewer, Charles F. Chandler, Wolcott Gibbs, and Ira Remsen, who state that the process by which glucose is made is unobjectionable, and that the product is in no wise inferior to cane sugar, save in the matter of sweetening power.

A UTOPIAN SCHEME.

As if there were not already enough medical colleges in the country, a bill has been introduced into the United States Senate providing for the establishment of a "University of Medicine." To support this proposed institution, an appropriation of a mill-

ion dollars is contemplated as an endowment fund. We are told that "allopathic, homœopathic, and eclectic methods are all to be represented by professorships." Besides the endowment fund, a further sum of a hundred thousand dollars is to be devoted to the purchase of land and the construction of the necessary buildings.

CARBON AND HYGIENE.

THE president of an hygienic society has discovered another deadly enemy to health—none other than carbon. According to this gentleman and his associates, most diseases have their origin in "biliousness," and that, in turn, is for the most part due to an excess of carbon in the body, and to the obstructions caused thereby. They object to the use of sweet milk as an article of diet, especially for sick people, on account of the carbon it contains!

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 15, 1884:

DISEASES.	Week ending Jan. 8.		Week ending Jan. 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	6	4	5	2
Scarlet Fever.....	88	2	81	14
Cerebro-spinal meningitis....	1	0	4	4
Measles.....	68	3	52	6
Diphtheria.....	59	11	33	9
Yellow Fever.....	0	0	1	1

THE HOSPITAL SATURDAY AND SUNDAY FUND.—Up to Tuesday, 175 of the 340 churches in the association had been heard from, and at that time the total received amounted to \$31,836.47. The account will be kept open until the first of February.

EGYPTIAN RAGS are likely to be subjected to inspection at the hands of American sanitary officials prior to their leaving Egypt, the inspectors to be appointed by the United States consuls.

THE ELLIS BEQUEST TO THE HARVARD MEDICAL SCHOOL.—Last week we recorded the fact of the late Dr. Calvin Ellis's having left the sum of \$50,000 to the school, under certain conditions. It is now stated that, in the event of the trust-fund amounting to more than that sum, the income of the excess, after deducting five per cent., is to be applied to paying a salary to the professor of pathological anatomy.

ST. LUKE'S HOSPITAL, OF ST. LOUIS, is to receive a legacy of \$10,000 by the will of the late Mr. Ralph Sellow.

THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS.—According to a newspaper dispatch, eight of the professors and all the students have withdrawn from the college, the trouble being attributed to financial mismanagement.

A MALICIOUS SUIT was lately brought against Dr. David Webster by one Dr. Robert H. Hayes, the action being for alleged malicious prosecution and false imprisonment, Dr. Webster having prosecuted Hayes for practicing medicine without compliance with the provisions of the law. Hayes sued for damages in the sum of \$50,000. The defense was that the defendant acted as president of the Medical Society of the County of New York in the matter, and that the result of the action brought by the society was only to compel Hayes to comply with the law. Judge Freedman directed the jury to find for the

defendant, and accordingly the verdict was rendered in Dr. Webster's favor.

THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.—We are informed that the membership in the classes this season has numbered seventy-two, being somewhat less than that of the New York institutions of a like character, owing largely, it is supposed, to the fact that both the University of Pennsylvania and the Jefferson Medical College have post-graduate courses, and therefore naturally receive the greater number of their own alumni who come to Philadelphia for advanced teaching.

SMALL-POX IN PENNSYLVANIA.—The disease was reported as prevailing to an alarming extent in Girardville last week. The schools were all closed on that account.

THE UNITED STATES COLLEGE OF MEDICINE AND SURGERY.—A charter having been applied for by an institution in this city under this title, it is stated that a committee of the Board of Regents of the University of the State of New York has reported adversely on the application, on the ground that the conditions prescribed by law have not been complied with.

THE GARFIELD MEMORIAL HOSPITAL.—At a recent meeting of the incorporators it was announced that the total cost of the property, together with the sums thus far authorized to be expended for improvements, would amount to \$49,500, and that a suit in connection with an estate, until lately pending in Philadelphia, had been decided in such a manner that the hospital had come into possession of the funds at issue. A board of directors was elected, including Dr. Samuel C. Busey, of Washington, and Dr. John S. Billings, of the army.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.—We learn that the college has taken a lease of a building in East Twentieth Street, between Second and Third Avenues, four stories in height, and having ninety-five feet frontage, into which it will move on or about the first of February. This will give ample room for the present work of the school, as well as for a hospital department, which, we learn, is to be established. Bedside instruction will then be given under the same roof with the regular courses.

THE NEW YORK OPHTHALMOLOGICAL SOCIETY held its nineteenth annual meeting on the 14th inst., and elected Dr. David Webster president, Dr. C. J. Kipp, of Newark, N. J., vice-president, and Dr. James L. Minor secretary and treasurer.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.—At the seventy-eighth annual meeting, to be held at Albany, February 5, 6, and 7, 1884, the president's annual address will be on "The Reciprocal Attitude of the Medical Profession and the Community," by Dr. Alexander Hutchins, of Brooklyn.

The following titles of papers, printed in the order of their reception, are to be placed before the Business Committee: Malignant Lymph-Adenoma, with Cases, Dr. L. S. Pilcher, Brooklyn; Dysmenorrhœa: its Treatment by Dilatation, Dr. W. W. Potter, Buffalo; Operation for Closure of the Hard and Soft Palate, with Results, Dr. A. Vanderveer, Albany; Value of Electricity in Diagnosis, Dr. L. E. Felton, Potsdam; The Treatment of Suppurative Otitis in Children, Dr. S. Sexton, New York city; A Case of Sympathetic Serous Iritis, with Remarks, Dr. D. Webster, New York city; Strangulated Hernia, with Reports of Five Cases treated by Operation, Dr. J. Chapman, Medina; Two Unusual Cases in Obstetrical Practice, Dr. W. C. Wey, Elmira; A New Method of Partial Exstirpation of the Cancerous Uterus, Dr. E. Van de Warker, Syracuse; Two Cases of Poisoning by Tansy, Dr. W. Woodward, Big Flats; Hæmaturia, Two Cases of Extra-uterine Pregnancy, Two Cases

of Rupture of the Heart, Dr. T. H. Squire, Elmira; Management of Face Presentation, Dr. E. L. Partridge, New York city; Morbid Somnolence, Dr. C. L. Dana, New York city; An Operation for correcting Deformity of the Auricle, Dr. O. D. Pomeroy, New York city; Rheumatic Joint Lesions of Children, Dr. V. P. Gibney, New York City; Biographical Sketch of the Late Dr. G. W. Bradford, Dr. C. Green, Homer; Orbital Cellulitis, Dr. T. R. Pooley, New York city; Biographical Sketch of the Late Dr. J. F. Jenkins, Dr. G. J. Fisher, Sing Sing; Poisoning by Potassium Chlorate, Dr. G. B. Fowler, New York city; Spontaneous Pyæmia, Dr. J. B. Todd, Parish; The Establishment of Hospitals in Small Cities, Dr. E. H. Parker, Poughkeepsie; House Sanitation—as it is and as it should be, Dr. W. F. Sheehan, Rochester; Croup as distinguished from Diphtheria, Dr. A. G. Crittendon, Clifton Springs; The Medical Society of the State of New York in its Relation to Sanitary Science and the Public Health, Dr. E. Harris, Albany; A Plea for the Pharmacopœia, Dr. L. Johnson, New York city; Canalization, as applied to Amputation of the Female Breast, to insure Primary Union under One Dressing, Dr. A. G. Gerster, New York city.

In accordance with the by-laws, authors of papers must arrange with the Business Committee both as to the hour when the papers can be presented and as to the time to be consumed in reading.

THE MEDICO-LEGAL SOCIETY.—At the annual meeting, held on the 9th inst., the President, Mr. Clark Bell, delivered his sixth inaugural address, after which Mr. John E. McIntyre was elected assistant secretary, to fill a vacancy. Thus completed, the list of officers for the ensuing year stands: President, Mr. Clark Bell; vice-presidents, Dr. R. Ogden Doremus and the Hon. Delano C. Calvin; secretary, Mr. Leicester P. Holme; assistant secretary, Mr. John E. McIntyre; treasurer, Mr. Andrew S. Hammersley; librarian, Mr. R. S. Guernsey; curator and pathologist, Dr. Andrew H. Smith; corresponding secretary, Mr. Morris Ellinger; chemist, Dr. C. A. Doremus; trustees, Mr. W. G. Davies, Dr. E. H. M. Sell, the Hon. M. S. Isaacs, Dr. J. C. Thomas, and the Hon. B. A. Willis; members of the permanent commission, Dr. Wooster Beach, Mr. Austin Abbott, Dr. R. J. O'Sullivan, the Hon. A. G. Hull, Dr. Edward Bradley, and the Hon. G. H. Yeaman. Dr. J. G. Johnson, of Brooklyn, read a paper on "Concussion of the Spine in Railway Injuries."

THE NEW ASSISTANT SURGEON-GENERAL OF RHODE ISLAND.—Dr. George H. Kenyon, of Providence, has been appointed assistant surgeon-general, on the staff of Governor Bourne, with the rank of lieutenant-colonel.

THE NEW YORK INFANT ASYLUM.—The following-named gentlemen have been elected on the medical board for the ensuing year: Dr. W. R. Birdsall, Dr. A. N. Bell, Dr. F. H. Bosworth, Dr. E. Bradley, Dr. C. L. Dana, Dr. G. B. Fowler, Dr. W. F. Mittendorf, Dr. W. J. Morton, Dr. H. G. Piffard, Dr. O. D. Pomeroy, Dr. F. M. Warner, Dr. H. Marion-Sims, Dr. J. L. Smith, Dr. C. F. Stillman, Dr. J. C. Thomas, Dr. W. H. Welch, and Dr. J. S. McNamara.

DISEASES OF ANIMALS.—By a letter from Dr. H. J. Detmers, published last month, it will be seen that the French demagogue, Bert, is too sweeping in his assertions concerning the disease-infected American hog. Bert is reported as quoting Dr. Detmers to the effect that diseased hogs passed his house in Chicago daily, and they were sold cheap and shipped to Bordeaux and Havre, France. Dr. Detmers distinctly denies having made such statements, and adds most positively that, during the last four months, he has examined four thousand hogs, and has seen

at least ten times that number in one of the most prominent packing-houses in Chicago, and has not seen the slightest trace of disease. The disease known as hog-cholera is not so prevalent as in former seasons. The statement of Dr. Detmers concerning the prevalence of disease in swine is very important.—*Sanitary News.*

THE "MEDICAL GAZETTE."—The publisher announced in the last issue for 1883 that with that number the "Gazette" ceased to exist. It has been succeeded by the "Æsculapian," a notice of which appeared in this journal for January 12th.

CORRIGENDUM.—In our issue of the 5th inst., in the report of the discussion on Dr. Partridge's paper (p. 22), Dr. Charles Jewett was said to have made this statement: "Of the thirty-six treated with thorough antiseptic precautions, only five had a temperature above 99°5' longer than one day," etc. It should have read as follows: "Eleven of the thirty-six patients had temperatures which exceeded 99°5' for one or more days in the first week."

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 5, 1884, to January 12, 1884:*

BROWN, P. R., Captain and Assistant Surgeon. Assigned to duty at Fort Huachuca, A. T. Par. 9, S. O. 119, Department of Arizona, December 27, 1883.

EGAN, P. R., First Lieutenant and Assistant Surgeon. Upon reporting of relief, to proceed without delay from Fort Huachuca, A. T., to Fort Apache, A. T., and report to the commanding officer for duty at that post. S. O. 119, Department of Arizona, December 27, 1883.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending January 12, 1884:*

MCMURTRIE, D., Surgeon, ordered to the Naval Rendezvous, Philadelphia, Pa.

PRICE, A. T., Surgeon, detached from the Receiving Ship St. Louis on the 15th, and ordered to the U. S. S. Ossipee on the 22d.

RUSSELL, A. C. H., Passed Assistant Surgeon, ordered to the U. S. S. Ossipee on the 22d.

ECKSTEIN, H. C., Passed Assistant Surgeon, detached from the Naval Hospital, Philadelphia, and ordered to the Receiving Ship St. Louis.

WELLS, HOWARD, Passed Assistant Surgeon, from the Naval Rendezvous, Philadelphia, and ordered to the Naval Hospital, Philadelphia.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, January 21st:* Medico-Chirurgical Society of German Physicians.

Tuesday, January 22d: New York Dermatological Society (private); New York Surgical Society (private); Medical Society of the County of Putnam, N. Y.; Jersey City Pathological Society.

Wednesday, January 23d: New York Pathological Society; American Microscopical Society of the City of New York.

Thursday, January 24th: New York Academy of Medicine (Section in Obstetrics); Harlem Medical Association; Brooklyn Pathological Society.

Friday, January 25th: Yorkville Medical Association; New York Society of German Physicians (private); New York Clinical Society (private).

Saturday, January 26th: New York Medical and Surgical Society (annual—private).

OBITUARY NOTES.

HENRY A. DU BOIS, M. D., OF NEW HAVEN.—Dr. Du Bois died last Sunday, in his seventy-sixth year. He was born in New York city, August 9, 1808, and in 1817 he entered the Military Academy of Louis Bançel, a royalist refugee of the first French Revolution. In 1822 he left the academy, and in the following year he entered Columbia College, from which he was graduated in 1827. He was graduated from the College of Physicians and Surgeons, New York, in 1830, and in the same year was appointed house physician to the New York Hospital. In 1831 he went to Europe to complete his medical studies, and returned to New York in 1834, and in 1835 he was appointed one of the physicians to the New York Dispensary. In 1840, on account of ill-health, he relinquished medical practice, and in 1854 he moved to New Haven, where he has since resided. He was a member of the Connecticut Medical Society, and an honorary member of the Medical Association of New Haven.

JOHN T. GILMAN, M. D., OF PORTLAND, ME.—Dr. Gilman died on Wednesday, the 16th inst., at the age of seventy-eight. He was graduated from the academic department of Bowdoin College in 1826 and from the medical department in 1829, and for several years past has been a member of the Board of Trustees of that institution. He has been president of the Maine Medical Association, and was one of the founders of the Maine General Hospital, and was said to have been the first to perform Cæsarean section in Maine.

Letters to the Editor.

SKIN-GRAFTING.

29 WEST THIRTY-FIRST STREET, January 5, 1884.

To the Editor of the New York Medical Journal:

SIR: The material which is removed from the sides of a ruptured perinæum, when they are vivified preparatory to uniting them, makes the best skin-grafts to be obtained from any source. They are half skin and half mucous membrane, and seem peculiarly adapted for this purpose. A far larger proportion of the grafts will "take" when this material is used.

Yours truly,

JOHN HARVEY GIRDNER, M. D.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held January 17, 1884, FORDYCE BARKER, M. D., LL. D., President, in the chair.

ANTISEPTIC DRESSINGS AS THEY ARE USED IN THE NEW YORK HOSPITAL.—Dr. ROBERT F. WEIR read a paper with this title. [See page 57.]

Dr. ALFRED C. POST, being requested to open the discussion, could add little to the exhaustive remarks by Dr. Weir upon the subject. He was fully convinced of the great value of antiseptic surgery, although he was not prepared to accept all the details of treatment that had been mentioned, or acknowledge

their necessity, especially in minor cases. It had seemed to him that in small wounds, if not involving important parts, it was not necessary to go through the whole formality of these complicated dressings; that is to say, in cases which were pretty sure to do well without it. As to the importance of perfect cleanliness and thorough drainage, there could be no question. There was one substance, which had been introduced by Kocher, of Berne, in the dressing of wounds, which he had found of great value in certain cases: he referred to subnitrate of bismuth, dusted on the wound with a pepper-box.

Dr. JOSEPH D. BRYANT had been watching the progress of antiseptic surgery since 1868, at which time he was interne in Bellevue Hospital. While he was in the hospital twelve cases of compound fracture were brought in, which were treated according to the antiseptic methods then commonly employed there. The wound was washed with a solution of one part of carbolic acid to eighty of water, and a dressing soaked in a solution of the strength of one part to one hundred and twenty was applied. A plaster-of-Paris splint was also applied. But two of the patients died. In one of these the injury had been a very severe one, and recovery could hardly have been expected to take place under any circumstances. During the past few months he had made use of the bichloride solution in his service at the Bellevue Hospital, the solution consisting of one part of corrosive sublimate to two thousand of water. In but one or two instances had suppuration developed in which it should have been prevented by the antiseptic, but in those cases the fault could be distinctly traced to negligence in carrying out the details. He had full faith in antiseptic methods of treatment, but he thought it important that the hospital surgeons should seek to give to the general practitioner a less expensive and complicated method than that which has been described by the author of the paper. As to the different antiseptic agents, at present the question seemed to rest between bichloride of mercury, carbolic acid, and, he might say, iodine. Different substances might be employed with advantage as dressings: peat, gauze, etc. He fully concurred with Dr. Weir in giving great credit and honor to Mr. Lister for the work which he had done in bringing antiseptics so prominently before the profession.

Dr. L. A. STIMSON thought the subject involved two distinct questions which should be borne in mind during the discussion: First, the causes of complications in surgical wounds, and, second, the value of antiseptic agents in the prevention or correction of the effects of those causes. The question did not alone involve the prevention of the development of germs or their entrance at the seat of the wound. If such were the only question, all that would be necessary to carry every case on to a successful issue would be the discovery of an efficient germicide, and its thorough application. It seemed to Dr. Stimson, however, that these complications could arise from other causes than the presence of germs, and what those other causes were was unknown. Every surgeon had met with cases in which all possible avenues for the entrance and the development of germs seemed to have been occluded, and yet sepsis developed. In illustration, reference was made to a case in which a man fell and injured the ankle. Nowhere on the surface of the body was the skin broken except at a small spot on the back. Yet within a few hours after the accident the ankle became swollen, there was cracking under pressure, symptoms of septicæmia developed, and, on amputating the limb, it was found to be infiltrated with pus. In this case there had been no opportunity for germs to enter and give rise to inflammation. If it were said they might have entered at the wound on the back, it would show the necessity of applying antiseptic dressings to every slight scratch which might exist

upon the body, however distant from the seat of the principal wound. If the result could be attributed to the germs taken in with the respired air, or with the food, it would show the impossibility of carrying out the principles of antiseptics in an effectual and practical manner. We were not justified, then, in asserting, as some surgeons had done, that by observing and executing faithfully the details of antiseptic treatment we should render the development of sepsis impossible. Instead of always attributing want of success to some possible oversight in the application of the antiseptic treatment, he thought we might better admit other possible sources of complication than the presence of germs. Moreover, it was not certain that the beneficial effect which had apparently attended the use of antiseptic methods had always been due to the germ-destroying properties of the dressings; it might be due to an unknown influence exerted by the presence of some one of the substances employed in the dressing. If we admitted that the presence of certain germs would give rise to sepsis, it did not follow that the presence of all germs would do so, or that all cases of sepsis were due to the presence of germs. It did, however, justify us in the employment of an agent which would prevent the development of germs capable of producing sepsis. Dr. Weir had stated that peat in itself had been shown to possess antiseptic properties, inasmuch as certain cases had done well when this agent in its natural state had been employed as a dressing to the wound. But certain experiments which Dr. Stimson had made went to show that peat was full of bacteria. Therefore, if it had exerted any influence in the prevention of sepsis, it had been by some other means than its germicide properties. He summed up his views by saying that he believed in antiseptics which purified the patient, the surgeon, the assistants, and the instruments. Further, he wanted drainage, compression, and rest.

Dr. ARPAD G. GERSTER believed that there were certain points which marked the corrosive-sublimate solution as superior to carbolic acid as an antiseptic agent. The latter agent produced a sanguinolent discharge from the wound surface fifteen to twenty-four hours after its application, and rendered a change of dressing necessary, with its attendant danger of giving rise to sepsis; it also frustrated one principle in treatment, namely, long-continued rest. The corrosive-sublimate solution, on the contrary, had no tendency to cause absorption of the newly formed blood-clot, and thereby give rise to a discharge demanding a change of dressing. He had been conducting tests of the value of certain substances for the dressing of wounds which could be obtained in this country, and consequently were cheap and could be readily procured for use by the general practitioner. Of these substances, sawdust soaked in a bichloride solution, one to five hundred, and afterward dried, had given the greatest satisfaction. It had proved fully as valuable and effective as any of the more costly and fanciful dressings. Ordinary cotton-wool, rendered antiseptic by the bichloride, had also been used with excellent results in a very unfavorable case occurring in an aged man, who had sustained a compound fracture at the elbow joint. Dr. Gerster was called to attend the injury, and was obliged to improvise his dressings, which he did by preparing ordinary cotton-wool with a solution of bichloride. The fracture, which was Y-shaped, was reduced, the dressings carefully applied, and the patient recovered without an unfavorable symptom. He referred to the importance of care in carrying out the antiseptic treatment, and the observance of strict cleanliness, and cited a case in which threatened suppurative after an operation at the shoulder joint was averted by opening the wound and discovering that the unfavorable symptoms were due to some dirty pieces of catgut, among those intended to establish drainage from the wound. He believed that not a

few of the failures were due not only to the admission of germs, but even to the admission of masses of dirt.

Dr. WEIR was reminded of the old fable of the golden and silver shield; one looked at it on one side and the other on the other side, but it was only a shield. He agreed with the remarks made by Dr. Gerster, and also those made by Dr. Stimson, although they apparently differed. Whenever there had been failure in his attempts to prevent the development of sepsis, he had searched carefully to learn the cause, and in some instances had been able to trace the source of the trouble, but in others, as Dr. Stimson had said, the cause could not be discovered. He had also raised his voice in warning against undertaking operations which hazarded life where but very little was to be gained. The subnitrate of bismuth was of value in certain cases, but it had not been largely adopted as a dressing, as it did not possess qualities preventing the development of erysipelas, like the other agents, other than iodoform, referred to.

NEW YORK SURGICAL SOCIETY.

(Concluded from page 48.)

Dr. LANGE said [in answer to the President's question, "whether, if suppurative and inflammation should occur, there would not be more or less impairment of the muscles of the jaw"—Dr. Gerster's paper being under discussion] he should think so, and that in some cases a certain degree of difficulty in mastication had followed the operation, but not sufficient to make it specially uncomfortable for the patient.

Dr. MARCOE said that, in thinking of these cases for many years past, he had been strongly impressed with the feeling that, if it could be shown that these most severe and more radical, more perfect operations for neurotomy were certainly successful in curing the disease, they would be justifiable; but his impression was that the operations which had been described by Dr. Howe and by himself were very much less dangerous, less severe, and productive of results which at least would compare favorably with those which had been recorded of the severer operations referred to by Dr. Lange and by Dr. Gerster. It might be a less perfect operation, but he could conceive that, if the scissors fell outside of the posterior dental nerve, all had been accomplished that could be done by excision of the nerve, and he did not believe that it was necessary to destroy Meckel's ganglion. His own feeling had been that these severe operations did not offer so much better prospect of success as to justify their performance, but at the same time he did not wish to dogmatize upon the subject.

Dr. H. B. SANDS said that within a year he had had occasion to perform Luecke's operation, not for the purpose of curing neuralgia, but with the intention of removing a tumor which was supposed to be situated in the sphenomaxillary fossa. The tumor was found where it was supposed to be, but was so extensive and so firmly attached that the operation for its removal was abandoned as impracticable. In that case the wound did well, and the bone became consolidated without necrosis. There was now to be noticed, about nine months after the operation, considerable difficulty in opening the mouth, but he believed this not to be due to the operation, but to an increase of the size of the tumor. He was certain that the operation proposed by Dr. Gerster, as well as the one referred to by Dr. Lange, excelled all other operations in the ease and certainty with which the parts lying in the sphenomaxillary fossa were exposed to view. Many years ago he performed Langenbeck's operation for the removal of a tumor situated in the sphenomaxillary fossa, and found that the end was accomplished without difficulty. He

would think the nerves in the same region might be removed with equal ease.

DEATH FROM ETHER.—Dr. E. L. KEYES reported a case of death from ether occurring in a colored boy upon whom he was operating in Bellevue Hospital for excision of the knee joint. The patient was about twelve years old, and was apparently in perfect health, except the disease of the knee, which had existed for a number of years. He took the ether at the hands of one of the house staff, and there was no untoward symptom for an hour or more. Dr. J. D. Bryant was present, and, after the operation was substantially completed, he felt the patient's pulse, pronounced it excellent, and left the room. About a minute later, the gentleman who was administering the ether said that something was wrong, and called attention to the facts that the boy was breathing faintly and that the pulse had disappeared from the wrist. Dr. Keyes at once resorted to all the usual measures for resuscitation, such as hanging the head over the table, artificial respiration, hypodermic injections of ether, ammonia, and brandy, faradization of the diaphragm, strapping the extremities, etc., and these efforts were continued for forty-five minutes, but without avail, as the boy was dead. Dr. Keyes thought that the boy was probably dead before he had time to resort to any measures for resuscitation. The autopsy was made by the house surgeon, who reported that all of the organs were normal. All the internal organs were intensely congested, and the heart was empty, having stopped in systole.

The ether used was that manufactured by Powers & Weightman; the quantity was nearly one pound. There was no mucus in the larynx, the patient had not vomited or attempted to vomit, everything seemed to be going on nicely, when suddenly death occurred by the heart.

Dr. LANGE said the only sad experience with ether he had ever had was in a female patient upon whom he had operated for a strangulated umbilical hernia. She had a weak heart at the beginning of the operation. A fit of vomiting occurred, the heart's action ceased, and also respiration. Tracheotomy was immediately performed and the trachea sucked out, but life was extinct.

Dr. SANDS thought it important to distinguish between those cases in which death occurred slowly from asphyxia and those in which it occurred suddenly from cardiac paralysis. In the latter class of cases it seemed doubtful whether there would be time to resort to any measures for restoration, as death took place sometimes almost instantly. If transfusion could be done in time it would be indicated in some cases. He recalled two cases of death from ether which occurred in the New York Hospital. One case was that of a stout, healthy man, who in the use of a pruning knife accidentally wounded his right carotid artery, and nearly lost his life upon the spot from profuse hæmorrhage. He was brought to the hospital in a state of exhaustion. Dr. Willard Parker immediately came to see him, called a consultation, and proceeded to expose the injured vessel. In that case Dr. Sands remembered that he had his finger upon the patient's pulse, which became imperceptible immediately after the incision had been made through the skin. The operation was suspended for a few minutes, some restorative was given, the pulse was again felt, and the operation was proceeded with. Then a second time the pulse stopped, the face became pale, respiration ceased, and all attempts at resuscitation proved unsuccessful. In that instance death was due to the excessive action of ether upon a heart already enfeebled by loss of blood, and therefore it might, perhaps, have been averted by a preliminary transfusion.

The other case occurred in the service of the late Dr. Allin, who was about to remove a tumor of the upper jaw from an old woman. The patient was in the sitting posture, and in that

case also, although the face had become somewhat livid from ether, just after the incision was made through the skin, before much blood escaped, the pulse stopped, and the heart's action was not resumed. The suddenness with which death occurred in such circumstances was very appalling, and seemed to give little encouragement for the employment of any attempts to restore animation. He believed that in Dr. Keyes's case death had already taken place when failure of the pulse was noticed.

The PRESIDENT said Dr. Allin's case excited a great deal of attention at the time, and observations determined that many of the deaths from ether occurred in connection with operations about the jaw and neck. This fact subsequently received a more scientific explanation from Schiff, who showed that, when animals were anesthetized, pinching the neck would arrest the heart's action and the respiration. Still, it was well known how safe ether was. While chloroform kills one in twenty-five hundred, ether killed only one in twenty-five thousand. Perhaps this low mortality with ether might be explained by the fact that, were it not for the warnings which ether gave, death would take place more frequently than it did.

Dr. Post said the only two fatal cases which he had seen from the administration of ether were those in which operations for the removal of tumors of the neck were being performed which caused considerable embarrassment of respiration. There was no blood nor vomited matter to account for the fatal termination.

The PRESIDENT added another case which came under his observation while he was an interne in the New York Hospital, that of a double incarcerated serotal hernia of immense size, which could be previously partially reduced, though usually filling the scrotum. The house surgeon gave ether and forced up the contents of the hernia into the abdomen, and the man ceased to breathe. Nothing was found on the autopsy to explain the sudden death, and the fact that the abdominal cavity was compelled to receive more than it was accustomed to, and thus the action of the diaphragm was interfered with, was received as the possible cause.

Dr. L. M. YALE referred to a collection of seven thousand cases of anesthesia in one of the English hospitals, and remarked that in all the instances where alarming symptoms had occurred it had been noticed that the patients who had been rolled upon the left side recovered, while those who had been rolled in the opposite direction died. Whether or not this was a general law was not stated, and he was unable to say.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of December 12, 1883.

PROOF THAT HUMAN MILK CONTAINS ONLY ABOUT ONE PER CENT. OF CASEIN; WITH REMARKS UPON INFANT FEEDING.—Dr. ARTHUR V. MEIGS read the following paper:

You must give me your indulgence for bringing before you a subject necessarily somewhat dry in its details, but its great importance must be my justification. Nearly two years ago I had the pleasure of reading here a paper upon "Milk Analysis," when I described the method I had worked out, and briefly detailed my results. The main conclusion was that human milk never contains more than about one per cent. of casein, and this observation I then claimed to be a new one, and very important, as showing how we should feed infants so unfortunate as to be deprived of their natural sustenance. A year ago or more I delivered a lecture to the class at the Pennsylvania Hospital, which was subsequently published in the "Medical News" of November 4, 1882, in which I described a plan of feeding deduced from the results of numerous experiments and analyses. This evening I wish, first, to offer proof that the results arrived at by the

milk had been previously ascertained to contain 788 milligrammes of sugar to each 100 c. c., which made its percentage of sugar 7.221, as already stated. These figures are sufficiently nearly parallel to prove the point, for, by the method of crystallization described, it was not expected that all the sugar present would be obtained in the crystalline form, some of it being necessarily precipitated with the casein in the course of the manipulations with alcohol; but only to obtain it pure, and in sufficient quantity, to prove that the sugar existed in the milk in the large quantity shown by the analysis, and therefore necessarily, by exclusion, the existence of only the small amount of casein. The demonstration thus obtained seems incontrovertible, for, when the existence of the large amount of sugar is shown, it follows as a necessary corollary that there can be only the small amount of casein, and therefore the existence of the small amount of casein in human milk is proved.

As a means of further proving that the sugar obtained by crystallization, as described, was entirely free from any traces of casein, it was tested for me by Mr. J. K. Hecker, the apothecary of the Pennsylvania Hospital, by the Nessler test described by Wanklyn and Chapman ("Water Analysis," by J. Alfred Wanklyn and Ernest Theophrastus Chapman, London, 1876, p. 25). This test decomposes the casein and forms ammonia from the nitrogen. When the crystalline sugar was subjected to its action, it showed it to be practically free from casein.

Cows' milk, when subjected to the same process of precipitation of the casein by alcohol, after the removal of the fat, yielded only about four or five per cent. of crystalline sugar. The manipulations were not carried out with the care that was taken when human milk was examined, for there is no dispute as to the amount of sugar in cows' milk; the experiment was therefore made merely to afford confirmatory evidence of what was shown by that upon the human milk. For if only a little more than four per cent. of sugar existed in human milk, as is claimed by Vernois and Becquerel, and others, and this being the quantity universally conceded to exist in cows' milk, then, when both were subjected to the action of the same reagents, the same amount only of crystalline sugar should be yielded. This, however, was not the case.

One of the strongest proofs of the correctness of the estimates of fat in milk is afforded by the fact that after it has been separated it can be seen, and the eye tells that it is fat. When sugar is crystallized, and can be seen and felt, and examined with the microscope or a magnifying-glass, and the characteristically shaped crystals of milk-sugar are seen, the fact that it is sugar, and nothing else, becomes self-evident.

To test still further the accuracy of the method described in my former paper upon milk analysis, I carefully analyzed a specimen of human milk and found it contained the different proximate constituents in about the usual quantities. Then I separated from a further portion of the milk, taken at the same time and under exactly parallel circumstances, fresh portions of the casein and sugar, which I gave to Mr. Hecker, to test their purity; the sugar to be subjected to the Nessler test, to discover if it contained any casein, and the casein to be subjected to the action of Fehling's test, to find whether or not it was free from all traces of sugar. The casein entirely failed to produce any effect upon the copper solution, thus showing that it was free from sugar, while, if a small portion of the sugar was added to the solution, the characteristic reduction of the copper at once took place. When the sugar was subjected to the Nessler test, .05 gramme being introduced into the retort when the decomposing materials were ready, it almost entirely failed to react, showing no more change than would be accounted for by the distilled water which had been used to prepare the sugar. This distilled water must have contained traces of organic matter; for

when it was subjected to the test it showed slight traces of ammonia. The test is so delicate that it is only by the greatest care and nicety in preparing the materials that they can be had perfectly free from all nitrogenized materials. The conclusion was that the sugars—both that prepared by the ordinary process advised for analytic purposes, and that obtained by crystallization—were, practically speaking, free from casein.

If, then, it has been shown that human milk contains approximately 87.1 per cent. of water, 4.2 per cent. of fat, 7.4 per cent. of sugar, and 0.1 per cent. of inorganic matter, the proof that it contains, not 3 or 4 per cent. of casein, as is commonly taught, but only about 1 per cent., is complete.

It may seem bold to make statements directly contradictory of the correctness of many of the usually accepted standards, but it is done with the full knowledge that it is liable to contradiction. There is an article on Infant Foods, by Professor Albert R. Leeds, in the "Transactions of the College of Physicians," third series, vol. vi, Philadelphia, 1883, in which he gives results quite different from my own; but, as he gives no account of the methods he pursued, any criticism of his results is at the present time impossible.

In the endeavor to find a food which shall be the best for infants who have to be hand-fed, there are two considerations, either of which might be selected as the basis from which to start. In the first place, the desired goal might be attained by making trial of all sorts of foods, and, these being put to the test of experience, the good would be retained and the bad gradually weeded out, until at last perhaps the most suitable would be found, and slowly introduced. On the other hand, the desired end might be attained by trying to produce a food which should be, as nearly as possible, like what nature has provided for the infant. Many trials have been made in the past by both these methods, but to the second one justice has never been done; for, if my conclusions are correct, a proper understanding of the composition of human milk, from which to start, has been wanting.

A clear understanding being now had of its proximate constituents, and the proportions in which they exist, it is possible more intelligently to set about finding how the same elements may be had, and mixed together to make an artificial food like human milk. Cows' milk is almost universally the basis of the foods used, in this country at least.

The artificial food which I shall presently recommend is the outcome of a study of the subject from both of the standpoints suggested, and its advantages are demonstrable. Upon theoretical grounds, it is what a food for infants should be; for analysis of human milk and cows' milk has shown what is their composition, and in the artificial food the elements have been introduced in the same proportions as they exist in human milk. Experience has for many years past been tending in the direction of proving such a food to be what is needed; for, while almost innumerable manufactured infant foods of every variety have been introduced, and have often for a time been thought all that could be desired, they have all, one after another, fallen into disuse and been forgotten; but the use of cows' milk continues to hold its own, and in civilized countries is employed ten times more than all the manufactured foods together. The question, however, remains of how to use it, and the various methods suggested have been almost as numerous as the physicians who have advised them. For a long time the great majority of writers upon infant diseases and diet have recommended that cow's milk should be diluted before giving it to young infants; and this, they all agree, is because it contains too much casein, which causes a curd that only infants of the strongest digestion can with safety assimilate.

The weight of testimony that cows' milk contains much

more casein than human milk is so great that it is astonishing how almost universally the analyses of human milk of Vernois and Bequerel, and of those who have arrived at like conclusions, have been accepted and given credence, in spite of the fact that the evidence of the senses of every one who has examined into the matter is diametrically opposed to such an acceptance. Although, as already said, the weight of authority has long been in favor of the use of diluted milk, still there have always been those who recommended it to be used pure. Of later years more and more has been said and written upon the advantages to be derived from the use of cream, or diluted cream. Dr. J. Forsyth Meigs, who was a well-known authority upon the complaints of children, for years used with great success a mixture of equal parts of milk, cream, lime-water, and a weak arrow-root-water, with a little sugar. Cream mixed with whey, to increase the sugar and lessen the amount of casein, has been recommended. Biedert (Virchow's "Archiv," Band 60, 1874) has written an article, and concludes that the best food is cream and water, one part to four with fifteen grammes of milk-sugar to the half-litre of the mixture, the strength of this to be gradually increased. Biedert made many experiments comparing the relative coagulability of human and cows' milk, and again the digestibility of the coagulum; as can therefore be presupposed, his experiments turned mainly upon the two kinds of casein and their differences. He concludes that "there are two important points in which human and cows' milk are unlike: first, in the different amounts of casein contained; and second, in the absolute chemical difference of the two sorts of casein. The first of these considerations would be of but little importance, however, if the analyses which place the average of casein in human milk at four per cent. are correct; its importance, on the other hand, would be very great if it usually contains—as I, in agreement with Vierordt's view, believe—only from two to two and a half per cent. I think many further analyses are necessary to establish this point absolutely. Even if this view is accepted, however, dilution of cows' milk with equal or more parts of water is not sufficient to remove the differences. It is well known that such a dilution does not remove all the disadvantages which arise in the use of cows' milk, and my clinical experience has taught me that even dilution with two parts of water does not attain the desired end; and the explanation of this positive irremovable difference is to be found in the important chemical differences which exist, the casein of cows' milk coagulating so much more easily and the coagulum being so much more firm than is the case with the casein of human milk; and, on the other hand, the coagulum being so much more difficult of solution or digestion.

"Until we succeed in actually making the casein of cows' milk identical with that of human milk, it will be necessary to give infants only so much of it as they can digest (no matter how great the necessary dilution may be), and to make up to them with carbo-hydrates (fat and milk-sugar) the lack of albuminates in the food." He further says: "After numerous experiments I have come to the conclusion that the amount of cow casein which an infant's food should contain is one per cent. The fat and sugar in cows' milk appear to be as easily digested as, and in no wise different from, those contained in human milk. If, therefore, one eighth of a litre of sweet cream (which, according to Hoppe, contains $9\frac{1}{2}$ per cent. of fat, 3 per cent. of sugar, and 4 per cent. of casein) is diluted with three eighths of a litre of water, which has been previously boiled, and milk-sugar is added in the proportion of 15 grammes to the half litre, the desired cream mixture is produced, and contains 1 per cent. of casein, 2.4 per cent. of fat, and 3.6 per cent. of milk-sugar, which will be found, under all circumstances, to be well borne, and is a sufficiently nourishing food." The greatest part of

Biedert's admirable article consists of a detail of experiments made of treating cows' and human milk, and the caseins obtained from both sorts, with a variety of reagents, and observing the different relative effects produced. His conclusion is "that the pure casein of human milk is, in both its physical and chemical nature, different from that of cows' milk." The casein of cows' milk, when isolated, has always an acid reaction, while, on the contrary, that obtained from human milk is always alkaline. If human casein is treated in a certain way with acid, there is produced an "acid modification of human casein," which has many points of resemblance with ordinary cow casein; on the other hand, by treating cow casein with alkali, a substance is produced which shows, with many reagents, identically the same changes that are, by like treatment, produced in human milk. After careful examination of these two substances, however, Biedert concludes that "cow casein treated with alkali is, in many respects, much more like human casein than the original cow casein, yet it always shows unmistakable differences." Although he makes a strong case, and there are many reasons in favor of accepting his conclusions, yet, in the present state of knowledge of casein, the difference can not be considered as absolutely demonstrated.

There are objections to such a belief; it has been already shown that human milk contains only one third the amount of casein that exists in cows' milk; and there is a further important difference, which Biedert also appreciates, that human milk is always alkaline, while, on the contrary, cows' milk is acid. A coagulum, therefore, produced in a solution which is relatively so concentrated as is the case in cows' milk, and, further, in a fluid which is acid in reaction, is a very much denser and larger one than can be had from the relatively weak solution in human milk; and it is quite possible, therefore, that the difference may be owing to the different degrees of concentration, and the difference of the fluid media in which the casein is held; it can not, therefore, yet be conceded that Biedert has absolutely demonstrated that the two caseins are chemically and physically different, although he has brought many strong arguments to bear. It is impossible to decide with certainty about casein in all its relations, while as yet it is not even known whether it is a simple or compound substance. Its solubility or insolubility after it has once been precipitated depends in great part upon how the original coagulation was effected, and whether or not it was thoroughly dried. If casein is once thoroughly dried for a good many hours at 100° C., it becomes absolutely insoluble in water, and will not dissolve even in a strong solution of caustic soda. Lehmann ("Physiological Chemistry," Cavendish Society Translation, vol. i, p. 378) says: "I believe that the jelly-like coagula of women's milk are more dependent on the alkaline state of the fluid than on any peculiarity in the casein; at all events, I have found that women's milk, when acid, yields a much thicker coagulum than when alkaline, and cows' milk, when alkaline, a much looser coagulum than when acid—facts of the highest interest and value in relation to dietetics."

Whatever may finally be decided about casein—whether those of cows' and human milk are as different as Biedert believes he has proved, or whether they are nearly alike, the difference being merely that the quantities are not the same and the containing fluid media different—what most concerns the subject in hand is the relatively small quantity which exists in human milk; for it shows conclusively that, in a food for infants, the amount of casein in cows' milk must by some means be reduced to equal the amount in human milk. The correct conclusion of Biedert, that not more than one per cent. of cow casein should be present in a food for infants, is the more surprising as he arrives at the opinion from a totally different reason from the true one that human milk contains only one per cent.

	Human. (Mean com- position from milk of 43 women.)	Artificial Food: Cream, 10 c. c.; milk, 5 c. c.; lime- water, 10 c. c.; water, 15 c. c.; sugar, 2-2 grms. (Cream con- tained 12-470 per cent. of fat.)	Artificial Food: Cream, 2 tablespoon- fuls; milk, 1 do.; lime-water, 2 do.; sugar-water, 3 do. (Cream contained 17-129 per cent. fat. Each tablespoonful was 20 c. c. Sugar- water was 174 drachms to pint.)	Cows' Milk.	Cows' Milk.	Eagle Brand Condensed Milk. 										Average from the 17.....	16-398

The human milk average is the result of ten analyses made. Eight separate analyses were made of the milk of different women; on another occasion, equal quantities of milk were taken from twenty-seven (27) women, and a portion of this analyzed; on a third, equal quantities of milk were taken from eight (8) colored women, and this subjected to analysis.

Although Biedert's conclusions are very instructive, as he arrives at them from clinical experience, and surprisingly correct in many respects, he goes astray in assuming an incorrect standard of the average composition of cream. The estimate of Hoppe, which he assumes to be correct, places the amount of casein too high; for, as may be seen by a reference to my table, cows' milk and cream do not contain more casein than sugar. The usual estimates rate the casein too high, at the expense of the sugar. This being the case, and Biedert reckoning the composition of his cream mixture from this incorrect standard, and not from any analysis either of the cream or the mixture itself, as should have been done, places his fat amount too low, as only a very poor cream is so weak in fat as his standard rates it. A mixture made as he directs is far weaker in sugar than human milk, and therefore, although perhaps proper for temporary use in cases of indigestion, can not be accepted as a standard of what an infant food should be; and it entirely fails to accomplish what he says should be done—make up to the infant by an excess of carbohydrates the lack of albuminates which exists in the food—for it only contains about half as much sugar as exists in human milk.

All these facts show that the tendency has been constantly toward the truth, and that physicians have been learning empirically for what reasons cows' milk has failed as an infant food, and how the difficulties which its use entailed were to be overcome. The use of cream has been advised; cream and whey; diluted milk; diluted milk with milk-sugar; cream, milk, lime-water, and arrowroot-water; and finally comes Biedert's cream mixture, and he arrives more nearly at the true solution of the difficulty than any of the others, but still falls wide of the mark, from want of a precise knowledge of the composition of human milk, and of cows' milk and cream.

Investigators have thus, year by year, and step by step, been approaching the desired goal, and it needed but a touch for light to be let in upon the whole subject. Many hours and much careful and patient labor have been expended in investigations in this field, and no single worker could have done his part without having the results of the labors of his predecessors before him, to guide him a long way in the field, and give him easily the knowledge which would enable him, after much toil and trouble, to advance one little step more toward what was

previously unknown. Thus, no individual investigator, no matter how important the advance in knowledge he may have made, should assume too large a share of credit; for it can be but a very small part of the great whole, and would be valueless but for the rest, into which it fits, and completes that which would otherwise be useless.

The necessary data being now at hand, it is comparatively easy to construct a food which shall, at least, be more nearly what is needed than any previous one. In making such a food, there are two matters to be considered: the proximate constituents must be in the same relative proportions as they are found in human milk, and they must be in a medium which shall be, as human milk is, alkaline. This latter end is easily accomplished by the use of a due amount of lime-water, and is justified by the fact that it is a matter of experience, almost universally acknowledged as true, that it is a most useful adjunct, rendering cows' milk more easy of digestion by the human stomach. The quantity of lime-water to be used should be one fourth of the total by measure. This may seem to many persons an excessive quantity, but when it is understood that if made as ordinarily directed, by agitating water with lime and then filtering, it contains only two decigrammes of lime in each litre, it becomes plain that the use of lime-water means the administration of a great deal of water and very little solid matter. The above estimate was arrived at by direct experiment; 10 c. c. of freshly made, filtered lime-water, being evaporated, were found to yield 2 milligrammes of lime. This is a very large estimate of the amount of lime soluble in water, as may be seen by reference to the "U. S. Dispensatory," or the "National Dispensatory," both giving it as much less. That the use of lime-water (alkali) in an infant food makes a difference in its behavior with some reagents is shown by the following experiments: A food was made in the proportions which will presently be given, and 10 c. c. of it agitated with ether and alcohol, as directed in my previous paper, read before the society, for the extraction of the fat; it was found that the coagulation took place in the form of a fine network, which remained permanently distributed through the lower stratum of the liquid, no sediment forming at the bottom. When an exactly similar mixture was made, except that the lime-water was replaced with water, leaving the fluid acid, and this agitated with ether and alcohol, thick, heavy curds

formed, which at once sink to the bottom. Again, when two mixtures—one with and the other without lime-water—were treated with 10 drops of acetic acid, the one without lime-water showed much larger, heavier coagula than that which contained lime-water. These experiments show with certainty that addition of lime-water does the alter the coagulability of the casein when experimented with, whatever may take place in the stomach; and I have already quoted Lehmann's opinion that the acidity or alkalinity of milk makes a difference in the formation of the coagulum. Whatever may be the value of these artificial experiments, the great reason for the use of lime-water is that the experience of man has found it good, and that is sufficient reason for its use in the present state of knowledge. It is quite possible that in the future something better may be found—phosphate of lime, perhaps, for it is the salt which exists in milk in larger quantity than any other; but further and exhaustive study of the inorganic constituents of both human and cows' milk will be required to place this matter upon an exact scientific basis. It is very desirable that further study of the salts of milk should be prosecuted, and it is much to be hoped that in the near future exhaustive analyses will be made. The amount of inorganic matter in cows' milk is so much greater than that in human milk that, as there is at present no means of removing it without altering or destroying the other component parts, no infant food can be made exactly like human milk in respect to the amount of salts contained.

So far as bringing the other proximate constituents to like proportions with those in human milk, the first step must be to so dilute with water as to get the desired quantity of casein; the fat and sugar can be increased by the use of the necessary quantities of cream and commercial milk-sugar. Taking the averages of cream and good city milk as already given (see table), it will be found by calculation that if there be mixed together 10 c. c. of cream, 5 c. c. of milk, 10 c. c. of lime-water, and 15 c. c. of water, with 2.2 grammes of milk-sugar, the desired mixture is had. That this is the case should not be trusted to mere calculation, but an analysis of the mixture should be made, both to verify the calculation and to observe how the mixture behaves when subjected to the analytic processes, whether it in its reactions more closely resembles cows' milk, with which it is made, or human milk. The table shows the results obtained by such analyses.

The easiest way to prepare and use the food is as follows: There must be obtained from a reliable druggist packages of pure milk-sugar containing seventeen and three quarters drachms each. The contents of one package is to be dissolved in a pint of hot water, and it is best to have a bottle which will contain just one pint, as there is then no need for further measuring. The contents of one of the sugar packages is put into the bottle, and, when filled with hot water, the sugar soon dissolves, and it is ready for use. The dry sugar keeps indefinitely, but after it is once dissolved it sours if kept more than a day or two in warm weather; it is understood, therefore, that the sugar-water must be kept in a cool place, and if it should at any time become sour, as is easily discovered if it is smelled and tasted, it should be thrown out, and, after the bottle has been carefully washed with boiling water, the contents of a fresh package dissolved. A milkman must be found who will serve every day fresh, good milk and cream. By good milk is meant ordinary milk, such as is easily procured in most cities, and not rich Jersey milk; and in the same way the cream should be such as is ordinarily used in tea and coffee, and not the very rich cream of fancy cattle. The reason that ordinary milk and cream are recommended is because they are within the reach of almost every one, and not because they are any better than the rich milk of high-bred stock. If Jersey milk was to be used, it

would be necessary to analyze specimens, and then make the necessary calculations as to how to dilute it to obtain the desired relative proportions of the proximate principles. When the child is to be fed, the nurse should mix together two tablespoonfuls of cream, one of milk, two of lime-water, and three of the sugar-water, and then, as soon as the mixture has been warmed, it may be poured into the bottle and the food is ready for use. If the infant is healthy, this quantity will not satisfy it after the first few weeks, and then double the quantity must be prepared for each feeding. Twice as many tablespoonfuls of each of the ingredients must be mixed together, making sixteen tablespoonfuls (about half a pint) in all.

This food should not be given any stronger until the child is eight or nine months old at least; but, if the infant is a healthy one, it may take as much of it as it wants, but always of the same strength. A robust infant will often take three pints, or even more, in each twenty-four hours. It is an easy matter for any one to learn how to make the lime-water, and it is advisable to have it made at home, for a great deal is saved, and, if it is made at home, much trouble and expense are saved.

With regard to the propriety of increasing, from week to week, the strength of any artificial food given to infants, there has been some question. Most authorities have advised that the foods should be increased in concentration until finally the infant is given pure cows' milk. The propriety of this procedure, during the earlier months of life at any rate, is very doubtful. Although there is some reason to believe that the quantity of solid ingredients in human milk increases from month to month as lactation goes on, such an opinion should be accepted only with great caution, for it seems likely that, if there is any increase in the concentration of the milk after the colostrum has once disappeared, and the nursing process has settled down into its even course, the increase is so slight that it may be disregarded. Analyses show that the milk of a woman whose child is two months old does not differ materially from that of one whose child is twelve or fifteen months old. If, then, nature has made no difference, which our means of analysis will detect, between the milk of a woman who has been nursing two months and one who has nursed twelve, an artificial food which has been found to suit an infant of two months should be made more concentrated only very gradually, and with careful observation of the effect upon the health of the infant. It is best, therefore, if the infant thrives and grows as it should, not to make any change in the food until after six to nine months of age have been attained.

With regard to the use of condensed milk as a food for young infants, I can only repeat what I said in my former paper, that I can not believe that any article which has been canned, and kept for weeks or months, or perhaps still longer, can be so good as the same thing when fresh. My table of analyses shows the composition of the dilution of condensed milk commonly used in this city, and it shows that the proportion of fat is much too small, and for this reason, partly at least, it fails as a food. Its success is due to the fact that it contains nearly the same proportions of casein and sugar as exist in human milk. Dr. Ellwood Wilson is in the habit of directing that after the first few weeks a small proportion of fresh cream be added to the condensed milk, and this would render it still more nearly what is needed; this practice, which can not be too much commended, if condensed milk is used, is not, however, at all a common one. Withal, I am unable to believe that condensed can be as good as fresh milk, if properly used. There are many other points of great interest connected with this subject which I should have liked to bring to your attention, but my paper has been already much too long.

The President called attention to the following points for discussion:

1. Any method of analysis which is to be generally accepted must be susceptible of verification.
2. All previous analysts agree about the amounts of water, fat, and ash; therefore, about the amounts of casein and sugar alone is there any disagreement.
3. Further, all agree about the sum of the amounts of these two elements (casein and sugar), but diverge widely about their individual amounts.
4. If it has been proved that, collectively, casein and sugar amount to about eight per cent., and that the sugar is about seven per cent., it then follows that the casein is only one per cent.
5. When subjected to the same method of analysis, human milk yields nearly seven per cent. of crystalline sugar, and cows' milk about four per cent.
6. To be able to make a proper food for infants, we must first understand the composition of their natural food—human milk.
7. Is there any great and important difference between the casein of human milk and that of cows' milk, except that it is contained in the latter in a larger proportion?
8. In preparing cows' milk for infants, clinicians usually direct that it be diluted, and some sugar and lime-water added; but more precision of advice is needed.
9. What is the best method of making an artificial food like human milk?
10. What is the propriety of increasing the nutritive quality of the food from month to month, as the child grows older?
11. What can be said of condensed milk as a diet for infants?

Dr. J. CHESTON MORRIS, in opening the discussion at the request of the Chair, said: It gives me great pleasure to pay my tribute of respect to the accuracy and industry which Dr. Meigs has so evidently exhibited in his investigations, though they have led him to very different results from my own. Accurate analysis, even of inorganic bodies, is difficult, as many of us know who have tried it; but accurate analysis of inorganic mixtures is far more so, from the changes continually going on in them.

A perfect method of milk analysis is probably not yet attained. Dr. Meigs having replied to a question from Dr. Morris—that he obtained the amount of fat present by repeated washings of the milk with ether and alcohol—Dr. Morris resumed: The extraction of all the fat present is difficult, owing to the globules being surrounded by a thin membrane of casein; this has been proved by Mitscherlich, who advises the previous agitation of the milk with a small quantity of solution of caustic potash, when the ether immediately dissolves out the fat. Perhaps the best process yet devised is that of the Society of Public Analysts of Great Britain, given at length in various numbers of the "Analyst."

The amount of water present in normal milk does not vary very much, nor does that of ash; but, judging from the report of over 12,000 analyses, made by Dr. Viette for the Aylesbury Dairy Company of London, that of the fat in cows' milk does vary from three per cent. to between five and six per cent. Any result less than three per cent. is regarded as proof of adulteration. So far is the amount of water, ash, and fat from being regarded as agreed upon among analysts, that the problem with them generally has been to obtain a method which would enable them readily to ascertain this latter factor; and Mr. Hehner has constructed, as a means to detect adulteration, a table showing the relation between the specific gravity and the fat present, the solids *not* fat (i. e., casein and sugar) being

taken as constants. To what extent these are really so may be judged from the analyses of Dr. Viette, above quoted, showing a maximum of 10.31 per cent. and a minimum of 8.97 per cent. in over 12,000 analyses. The total average is about 9.5 per cent. in cows' milk. But all cows' milk is not alike; that from different breeds has marked peculiarities and differences, perceptible even to the eye and the taste. The milk from the Jersey cow is rich in fat, but poor in casein and sugar; that from the Durham is comparatively watery, and poor in fat and sugar, though relatively rich in casein; that of the Devon is nearly as rich in fat as that of the Jersey, and in casein as the Durham, and richer in sugar than either of them. The commercial uses of these breeds in butter- and cheese-making bear out the above statements.

Another reason for thinking that one per cent. is too low an estimate of the amount of casein in human milk is, that such a proportion would hardly supply the needed amount of nitrogenous food to the infant. Lehmann tells us that the amount of milk secreted daily by the human female may be estimated at 2.2 per cent. of her weight; so that a woman of 150 pounds would produce 3.3 pounds milk, or 23,100 grains—rather more than a quart and a gill. If only one per cent. of this is casein, it would give only 231 grains; if she weighed only 120 pounds, there would be only 2.64 pounds milk, of which only 185 grains would be nitrogenous. Authorities on diet tell us that the human being requires food amounting to one twenty-fourth to one twentieth of his weight, of which one fifth, or one per cent. of the whole, should be nitrogenous. Applying this rule to the infant, which has certainly larger needs for food for development, a weight of 10 pounds, or 70,000 grains, would require 700 grains of nitrogenous food—a figure nearly approximating that which would be yielded by a milk containing three per cent. of casein. In colostrum, however, we have a fluid poor in casein, but rich in sugar and fat.

Casein and sugar, we are told by Lehmann, are both soluble to some extent in alcohol. I have studied the question of the identity of casein of cows' and human milk, without being able to fully satisfy myself, but am inclined to regard them as differing mainly in coagulability. This may depend on the salts with which they are associated, as may also the acidity or alkalinity of the milk. These salts have, relatively to the serum of the blood, a preponderance of phosphates and potassium salts to the chlorides and sodium salts; and the acidity or alkalinity of cows' milk is influenced by their food. As a rule, I believe it is alkaline.

I am in the habit of directing, as food for new-born infants, a mixture resembling colostrum—one part cows' milk to two or three of water, with a little sugar, for infants of two to six months; equal parts of milk and water, warmed and sweetened, for infants over six months; two parts milk and one of water, etc. As to quantity and frequency, much must depend on the child.

Dr. PARRISH: I can not pass judgment upon the chemical question, but the matter of substitutes for human milk is one that I am brought face to face with every day in private practice and in public institutions. I have had but little successful results with any of the prepared foods in the market, except condensed milk. I have frequently been called to see infants who have been seriously sickened by the use of such foods, or by other ill-advised articles of infant diet.

If I have the care of a child from birth, who is to be brought up without human milk, I begin with condensed milk; during the first few days I direct that one heaped teaspoonful should be dissolved in thirty teaspoonfuls of water; about the end of the first week one teaspoonful of the milk in twenty-five of water; at the end of a month one teaspoonful in twenty of

water; at about the end of the second month I have added one fourth cream; at the eighth month a change is made to cows' milk, diluted with one third water, with occasional use of beef-tea, etc., according to the age.

I do not think a child using condensed milk for sixteen or eighteen months continues to thrive so well as if the method stated were resorted to. Cows' milk is unsafe for young infants in the cities.

The addition of cream is advantageous by overcoming constipation accompanying the use of condensed milk, and by contributing very perceptibly to the nutrition of the infant.

If a child, dependent chiefly on cows' milk, is taken sick with bronchitis or any febrile disease, or with any digestive derangement, I recur to condensed milk as a sick diet.

Dr. MEIGS, in closing the discussion, said: I do not see that anything has been said to disprove what I have advanced, which was, substantially, that if analysis shows the water, fat, sugar, and salts of milk to equal a certain amount, then the casein can only equal the difference between that amount and the total quantity of milk taken. We know that these four substances are, and can identify and estimate them. What casein is, however, is not yet fully understood, but we can not escape from the conclusion as to its small amount in human milk, unless the process of analysis be shown to be erroneous in regard to some one of the other four constituents. I have noticed, incidentally, that the clear ethereal solution of the fat of milk sometimes lets fall a precipitate after standing. This I at first thought to be casein, but, as it melted when warmed, it must be some one of the forms of fat, but is insoluble in ether.

I do not think that the specific gravity is any guide as to the composition of milk. Mr. Wanklyn has shown its utter unreliability; nor do I think that we can distinguish the different amounts of sugar or casein in milk by the difference of taste or amount of coagulum. Milk-sugar has very little sweetish taste. The composition of milk is tolerably constant; it is not subject to such large variation within normal limits as urine is. Milk does vary much in its amount of fat. That first drawn from a woman who has not nursed her child for some hours will usually contain only two or three per cent. of fat, while that taken just after nursing may contain nine per cent.

As regards the amount secreted by women, very absurd statements—much below the proper figure—have been made by some of the older authorities, but Dr. John F. Meigs succeeded in one case in getting as much as three pints in twenty-four hours.

The salt which exists in largest quantity in milk is sodium phosphate. Cows' milk is almost always acid, while human milk is almost always alkaline in reaction.

Most authorities agree that cows' milk must be diluted when used for infants. Why is this, if not because the casein is less in human milk?

I agree with Dr. Parrish that most of the prepared foods are not good. Condensed milk is largely used by physicians in this city, and I believe its success is due to the fact that it gives only about one per cent. of casein as usually directed to be given. Condensed milk contains about fifty per cent. sugar. It is not unlikely that some of the milk-sugar is removed from it. Milk-sugar and casein are entirely insoluble in absolute alcohol, and alcohol will only take up very small quantities of milk-sugar as it becomes dilute, and only when it is very dilute will it take up any considerable amount.

My effort has been to place the demonstration of the amounts of the different constituents of human milk, so far as possible, upon a mathematical basis; and unless it can be shown that the estimates of some one of the four constituents—water, fat, sugar, or salts—are wrong, then it has been proved that human milk contains only the small amount of casein stated.

Miscellany.

THERAPEUTICAL NOTES.—*The Symptomatic Treatment of Paralysis Agitans.*—Erlenmeyer ("Centralblatt für Nervenheilkunde," 1883, No. 9; "Gazette hebdomadaire de médecine et de chirurgie," Dec. 28, 1883), after remarking that hydrate of chloral, morphine, bromide of potassium, nitrate of silver, and curare are of no avail in this affection, states that, on the contrary, the constant galvanic current, applied to the head, in the neighborhood of the nucha (feeble currents, continued from five to twenty minutes), together with the use of a combination of atropine and ergot, is followed by decided amelioration. About half a grain of sulphate of atropine is made into a mass with fifteen grains of extract of ergot, and the mass is divided into thirty pills, of which one is to be taken daily. Pure crystallized hyoscyamine the author regards as both too costly and too dangerous.

Quasi-poisonous Effects from White-Precipitate Ointment.—In the "British Medical Journal" for December 29, 1883, Mr. Shirley Deakin, of the British service in India, reports two cases of eczema which were aggravated by the use of an ointment of white precipitate, thirty grains to the ounce. In both cases the eczema was of the chronic, dry variety, and in both it was rendered acute and inoculable, so that the patients, by scratching, conveyed it to other parts of the body. It was found that both patients had obtained the ointment from the same apothecary, and the idea was entertained that the preparation was defective, but the pot from which it had been dispensed was nearly empty, and none of those who had previously been served from it had experienced any unusual effects. Mr. Deakin mentions the tendency of hydrargyrum cum creta to undergo oxidation in India, but states that he has never before known white precipitate to give rise to poisonous effects.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.—The annual meeting of this society will be held at Philadelphia on May 14, 16, and 18, 1884, in the Assembly Room of the Union League, Broad and Walnut Streets. The President's reception and the entertainment by the Philadelphia County Medical Society will be held on the evening of May 14th, at the Pennsylvania Academy of the Fine Arts, Broad and Arch Streets.

The by-laws require the programme of the meeting to be printed and distributed at least one month before the date of the meeting, and no voluntary paper is allowed to occupy more than twenty minutes in its reading.

Notice is hereby given that all those who wish to present papers should send the full title and a short abstract of the same to the Committee on Arrangements on or before March 1, 1884, in order that a varied and attractive programme may be prepared.

No paper will be selected for a position upon the programme of the meeting unless an abstract has previously been seen by the committee.

By order of the Committee, JOHN B. ROBERTS, Chairman,
1118 Arch St., Philadelphia.

THE MEANING OF THE TERM "GOOD HEALTH" IS LIFE INSURANCE.—A recent case in the Court of Appeals of this State is interesting as defining the term "good health" in an application for life insurance to mean that the person is well to ordinary observation and outward appearances. The Court said, in the opinion: "The question put and the answer given related not to the applicant's own health, but to that of a third person. Unless in rare and exceptional cases, the applicant, answering, could only answer from physical appearances and indications. He could not have the knowledge that an individual has of his own condition, and even in such cases self-deception is not rare, and very often entirely innocent and honest. Such an inquiry and its answer must necessarily be understood in a general and ordinary, and not in a strict and rigid, sense. One who is not a doctor, and speaks not of himself, but of a third person, necessarily gives rather an opinion founded on observed facts than an absolute and accurate fact when he describes the health of such person as good. He means, and is understood to mean, that the individual inquired about has indicated in his action and appearance no symptoms or traces of disease, and, to the observation of an ordinary friend or relative, is in truth well. He means that, because he can not usually mean anything else."

Lectures and Addresses.

A CLINICAL LECTURE IN GYNÆCOLOGY,

DELIVERED AT THE COLLEGE OF PHYSICIANS AND
SURGEONS, NEW YORK,

By T. GAILLARD THOMAS, M. D.,

CLINICAL PROFESSOR OF DISEASES OF WOMEN.

(REPORTED BY H. H. SEELYE, M. D.)

The Causes and Treatment of Abortion.—Persistent Sterility.

CASE I.—GENTLEMEN: The first patient this afternoon is Mrs. E. C., twenty-two years of age, and a native of the United States. She has been married three years, and has had no children, but has had three miscarriages.

I ask her how long she has been sick, and she replies that she has never been sick; and, as you look at her, you will believe her statement, for she has a strong and healthy appearance. So I ask her next why she has come here to see us, and she answers, because she is anxious to bear children; and, though she has been pregnant three times, she has had a miscarriage every time. She passed two years of her married life without becoming pregnant at all, and then she became so, but had a miscarriage at the end of three months. She knows of no cause for this miscarriage. In her second pregnancy she miscarried a little short of three months, but without any known cause. She became pregnant a third time, and again miscarried at about the same period as before. At none of these times does she remember to have had a fall, or to have made any violent effort, or any slip or misstep, or to have had any sudden fright, or anything else which she could assign as a cause of her miscarriages. All three of them have taken place within the past year. She complains now of no headache, or backache, or any other pain, and she walks easily and seems to be in perfect health.

Now, I show this case to you not because it is a remarkable one, for you will hear such a story as this over and over again, but because I like to show you here, not cases that are rare and such as you will seldom see elsewhere, but rather cases that are types of classes of such mild conditions as you will often meet with but which will cause you much trouble.

The history you have just heard here is one that you will hear repeated by patients again and again till you get sick of hearing it, and a patient will come back to you eight, ten, or twelve or more times, perhaps, complaining of repeated miscarriages every time, and appealing to you to help her, and, if you fail in your efforts, apparently holding you responsible for her misfortune. And let me tell you here that among the nineteenth-century women there are two classes—one, those who desire, above all things, to become pregnant and bear children; and the other, those who are anxious, above all, not to bear children. Now, this woman is thoroughly unhappy because of her sterility, and she is exceedingly anxious to bear chil-

dren. Now, forget for a moment where you are, and let us suppose that your patient is a lady of a great deal of wealth and the disposition of a large estate, perhaps, depends on her having a child, and you can imagine how unhappy she would be if she had only repeated miscarriages, and how important it would be for you to find out and, if possible, remove the causes of this mishap. In general, it may be said that miscarriages occurring at the third month are due to one of two causes more than to any others.

But first let me tell you, what you already know, no doubt, that out of one hundred cases of miscarriage more than seventy-five will occur at the end of the third month, and the next largest number at the end of the second month, and the next at the end of the fourth month, and the rest of the number will be scattered about in all the other months. That is to say, that over seventy-five per cent. of all cases of miscarriage occur at the end of the third month of gestation. There are two explanations of this fact. The first reason for it is, that at this time the placenta is just becoming thoroughly formed, while the chorion is disappearing and the manner of the nutrition of the child is changing, and, instead of being localized in the chorion, which receives its blood from the whole intra-uterine surface, it is becoming localized in the placenta, which draws its nutrition from a limited surface of the uterus; and, as the chorion degenerates and the placenta is forming and attaching itself more intimately to the uterine walls, the changing from the chorionic to the placental nutrition of the fetus is marked by a strong tendency to miscarriage. In the second place, you know that at the end of the third month the uterus is becoming so large that it is just beginning to rise out of the pelvis, and at this time, as the body of the uterus rises above the brim, if its supports happen to be a little weak, it is very apt to turn over on itself either to one side, or forward, or backward; and by this means the nutrition of the fetus is deranged, and hence this is a very frequent cause of miscarriage at this time.

Now, we will go back to the point at which I digressed and where I was saying that there are two great causes, not to mention the numerous possible causes, of habitual abortion in certain women. 1. A posterior displacement of the uterus which interferes with the proper development of the organ. 2. Syphilis. These are the two main causes; but now I will give you some of the others, merely in order to impress these two on your memories. You will sometimes find in a woman who has previously borne children that a slight single unilateral laceration of the cervix will become very irritable during pregnancy, and the reflex irritation thus caused will set up uterine contractions and bring about the expulsion of the fetus; and this will cause, perhaps, three or four abortions in the course of a year. Again, large granules will form on the cervix of some women every time they become pregnant, and these will set up enough irritation to cause an abortion. These granules sometimes resemble an epithelioma in appearance, and they are frequently mistaken for this by inexperienced physicians; but that they are not such is shown by the fact of their disappearance after every

abortion. Again, more accidental causes will produce a miscarriage in some very nervous women, and these are commonly spoken of as women who "habitually abort." But this term is too frequently applied where the physician has overlooked the true cause, and it is therefore usually only a cloak for his ignorance. Some time ago I had my attention called to a peculiar case of abortion from purely nervous influences as a first cause. The patient was a lady near the fourth month of pregnancy, who was traveling in the railroad cars with her husband. As the engine drew the cars suddenly into a dark tunnel, the roar of the train, multiplied by the echoes of the walls of the tunnel, awoke her from a sound sleep; the noise and the darkness made her believe that an accident had happened, she became greatly frightened, very soon after labor pains came on, by the time she had reached the end of her journey the uterus was contracting violently, and soon after arriving home she aborted. I was fortunate enough to preserve the placenta, and, upon examining it, I found that she had had a small placental apoplexy, and a clot of blood of the size of a walnut had formed and separated the placenta from the uterine wall, and from this focus an irritation had spread till it brought on uterine contractions which ended in an abortion.

So, also, it may be caused by a woman's measuring the height of a chair with her eye, and then unexpectedly sitting down to find it three or four inches lower than she had supposed it to be, the sudden jerk being sufficient to bring on uterine contractions. Instances are on record where such a simple matter as blowing out, instead of snuffing out, a candle, by reason of the disagreeable odor of the smoke, has caused a miscarriage; and I do not doubt that such trivial circumstances will sometimes induce it. These are all exceptional cases, and hardly to be considered. But the rule is that, in the great majority of cases where a woman has repeated miscarriages at the third month, you will find upon examination either a posterior displacement of the uterus, or that there is evidence of constitutional syphilis in the father or mother; or you may find both these conditions.

Now, this woman's husband is not here, so we can not examine him at present for symptoms of syphilis; but she says he is a healthy man, and has promised to bring him here to our clinic next week, so that we may inquire into his condition for ourselves. I think he will come, for he, as well as she, is anxious to have offspring. So we will have to wait till then to determine whether this cause for the repeated miscarriages exists here.

But there is another cause than this which will account for the miscarriages in this case. When I make a vaginal examination with this woman standing in the erect posture, I find that the uterus is bent backward toward the hollow of the sacrum, so that the greater part of the organ lies posteriorly to a line drawn perpendicularly down through the center of her body. You may ask if I think that this slight degree of displacement backward is sufficient to account for these repeated miscarriages; and I reply that I think this is a sufficient cause. Then you may ask: "How do you suppose that this insignificant cause can produce such a result?"

It would not as it is now, for that uterus is not badly displaced, but is lying only a little posterior to the central line drawn perpendicularly through her body, and, if it would keep the same position as now, it would be of no account either in a pregnant or non-pregnant woman, and no miscarriage would take place. But I will show you what occurs after pregnancy in such a case as this. At the end of the first month the uterus is slightly enlarged and its increased weight has caused it to bend over on itself still more, and so the posterior displacement is a little greater than before. At the end of two months the displacement is so great that the axis of the uterus forms almost a right angle with the perpendicular line drawn through the center of the pelvis; but even now there is no interference with utero-gestation, and the pregnancy goes on. At the end of the third month, however, when the body of the uterus has increased so much in size that it fills up the cavity of the pelvis as it lies displaced in the hollow of the sacrum, the uterus tries to rise up out of the pelvis, and the cervix does go up, but it can not pull the body up after it, because it is held down by the promontory of the sacrum, and only some lucky accident can release it. The rule is, however, that the cervix rises up, but nothing can get the uterine body out of the hollow of the pelvis; and yet, under certain circumstances, the organ will go on developing for four or five months, perhaps, without interference with the nutrition of the fœtus. But usually at the end of the third month the uterus feels the interference with its development, and so it begins to contract, and the cervix opens and labor goes on until the fœtus is expelled. Three months after, the woman goes to a doctor, perhaps, and asks him the cause of her miscarriage; and he examines her and finds the cervix all right and the uterus lying in the position I described to you as existing in this case at present, with only a slight posterior displacement, and he is at a loss to account for her misfortune. But the real cause of all was that, at the beginning of pregnancy, the uterus was lying a little posterior to a line running perpendicularly through the center of the woman's body; and you will almost invariably find that the slightest displacement posterior to this line will cause a miscarriage at the third month. Now, this exists in this woman at present, and it may possibly be the cause of her miscarriages; but before deciding I will examine her husband also. If I find that he has had constitutional syphilis, I will say that I do not know whether this displacement of the uterus is the main cause or not; but I will first remedy the condition I find already existing in the woman, and then I will treat the husband for syphilis, if I find it necessary, and I will try to keep him and the woman apart for a number of months, until I think he is entirely well and can impregnate his wife without transmitting the disease to the child. Even if I find syphilis in him, I will nevertheless treat the difficulty I find in her at the same time.

After the woman has again become pregnant I would watch her carefully as she advances, and have her come to me every four or five days or, at the longest, once a week, that I might see if every week of utero-gestation was increasing the displaced condition of the uterus. If, by the

end of the second month, I should find it bent farther backward than at the end of the first month, I would place the patient on her side or in the knee-chest position, and, with my fingers, push the uterus over into its proper place, and put in a pessary to keep it in position. Supported in this way, the uterus is able to rise up out of the pelvis as it enlarges, and pregnancy is therefore allowed to go on. If you try this plan of treatment in such cases you will often have reason to feel well satisfied with the results.

Let me tell you of a case I treated some twenty-five years ago. A lady came to me who said that she had had twelve miscarriages in succession. I examined her, and found just such a condition as we have in this case. None of the doctors who had previously examined her had discovered the presence of this displacement, because she had gone to them after each miscarriage, when the uterus had returned to its proper position. She was almost insane from these repeated disappointments. So, after she had again become pregnant, she came to me at the end of the third month of gestation, and I easily recognized a decided posterior displacement. To remedy this, I pushed the body of the uterus up above the promontory of the sacrum and put in a pessary to keep it there, and I had her return every two or three weeks so that I might adjust the pessary and see that everything was progressing favorably. She was delivered of a living child at full term, and she went on from that time through four successive pregnancies without having a single miscarriage, and this plan of treatment was carried out each time. Now, I do not say that a single case proves the efficiency of this plan any more than that "one swallow makes a summer." But I have had a whole flock of just such "swallows," and they have abundantly established the effectiveness of this treatment. I am talking now, remember, only of miscarriages occurring at the end of the third month, but they will form 75 to 80 per cent. of all the cases you will meet with. The moment I see a woman who tells me that she aborts regularly at the end of the third month, I am so certain of the cause that I say to myself that she has either a slight or a great displacement of the uterus, or else there is syphilis in the family. So, in case I find no displacement of her uterus, I always look carefully for any signs of syphilis in the husband or in the woman herself. And remember, gentlemen, that syphilis sometimes creeps into the system of a perfectly virtuous woman, and no one knows how it got there. Syphilis certainly develops accidentally sometimes, and I think it is a mistake for some physicians, who ought to know better, to laugh at the statement of a man who, when asked where he got his syphilis, says that he caught it from a privy, or in some other unusual way. I see nothing to laugh at in such a statement, and it seems to me that the joke is entirely out of place, for I do not see why the disease may not occur from such exposure. I have known of the case of a sewing woman in this city who became infected with a true Hunterian chancre, followed by a secondary eruption, apparently in the following way: she accidentally pricked herself in the breast with a pin which had probably retained upon it syphilitic virus from the hand of the woman in France who had made it, and who had doubtless just been dressing her chancre previously to stick-

ing the pin on the paper to send to this country, where it was destined to infect her innocent sister.

Now a few words in regard to another class of cases besides those which occur regularly at the end of the third month. In this class the mother passes safely through the early months of pregnancy, but at the end of the seventh month, perhaps, she notices that the movements of the child *in utero*, which have previously been vigorous enough, are now becoming more feeble, and the next day they are feeble still, and so on till in a few days they have ceased altogether, but she goes on to full term and then brings forth a dead child. This thing may have been repeated six or eight times before she comes to you to seek for the cause and its cure. If you examine the placenta at the completion of one of these labors you will almost invariably find that it has undergone a fatty degeneration. The only way of preventing this woman from constantly bringing forth still-born children is to tell her to watch carefully during the latter months of pregnancy, and to let you know as soon as she feels that the child's movements are beginning to lose their vigor, and then you should immediately induce labor and bring on a premature delivery. If it is in the seventh month, you may be able to preserve the life of the child, and your success will be more assured if delivery can be postponed till the end of the eighth month, or for eight and a half months. But the rule should be, the moment you find the child is in danger of death by reason of the degeneration of the placenta, bring on labor.

CASE II.—The next patient is Mrs. A. E., thirty-seven years of age, a native of the United States, who has been married eighteen years, and been sterile all through her married life.

She says that she has been sick for ten years, and she complains chiefly of a tired feeling all over the body, and of general weakness and lassitude, with much pain in the back and neck. She is regular in her monthly periods, but at such times she suffers from pain in the head and breasts. She also has a constant watery looking, but thick and tenacious, discharge from the vagina. She complains of nothing except a pretty severe cough.

Now, without an examination this is a perfect enigma, gentlemen, and so you will find with many, many cases; and, when a man is so squeamish that he thinks it a crime to examine a woman unless he suspects some very serious condition, I do not see how he ever gets on in practice. At one time not long ago, you know, it was generally thought that an unmarried woman ought not to be examined except in very unusual cases; and I am sorry to say that there are still some who carry out this belief, and thereby make themselves responsible for much misery that might otherwise be relieved if the cause were discovered. I constantly am making such examinations in young women of sixteen and upward, and I never hesitate where I am in doubt as to the cause of any serious difficulty.

This patient is healthy looking, but she has an appearance of lassitude, and she complains of great pain in the back and a sense of discomfort and weariness, which she dates back as beginning ten years ago. In addition, her sterility is a source of disturbance, together with a profuse

leucorrhœa and occasional pain in the head and breast. Now, you might investigate this case, with only the rational signs to help you, for any length of time, without obtaining any light as to the true condition present; but, when you make a physical examination, a flood of light is thrown over it at once.

This is what such an examination reveals: As the woman lies on her back, on passing my finger up the vagina I find the uterus is thrown over backward, and with one finger on the cervix and the fingers of the other hand pressing down through the anterior abdominal walls, I discover a large tumor lying on the upper side of the uterus between its fundus and my hand, which appears to be three or four times as big as the uterus itself, rounded in outline, and moving with the uterine body. How could you ever have told what was there without an examination! The man who would prescribe for that woman without making an examination is one of two things. He is either an ignorant or a dishonest man.

Now that we have found out the presence of a hitherto unsuspected tumor here, the question arises, "Is that the diagnosis?" There is the mass which, when carefully examined, would leave some doubt as to its character did we not have a history to aid us which points to a uterine fibroid. But is that the whole diagnosis? By changing the position of the patient so that she lies on her side, and putting in a Sims's speculum, from the cervical orifice could be seen poured out a secretion of thick, tenacious mucus. I passed a small sponge, held in a pair of forceps, up to the cervix and twisted it about, and, on withdrawing it, I could pull this mass of mucus down to the mouth of the vagina, when it broke and sprang back like a piece of India-rubber. Then I said that is the immediate cause of the sterility, as such discharge always is when it is found habitually pouring out of the cervical canal. This was doubtless caused by the malposition of the uterus, which, from lying back in the hollow of the sacrum, was kept in a state of chronic congestion, giving rise to a chronic endometritis. Now let us return to the tumor and inquire again what it may be. The abdominal walls are so thick that I could not map it out accurately, or tell whether there was any fluctuation in it or not. Now I ask, May this not be an ovarian tumor? As a rule, women with ovarian tumors become greatly exhausted within three years. Yet there are exceptions to this rule. Three months ago I operated at the Woman's Hospital for a tumor which Dr. Sims had, twenty-four years ago, declared to be an ovarian tumor of the size of a cocoanut. When I removed it, it weighed sixty pounds, and the woman got perfectly well after the operation. This tumor had unquestionably been growing for at least twenty-four years. The same week I removed another ovarian tumor that had been growing fifteen years. Fourteen years ago it had been tapped for the first time, and since then this operation had been repeated sixty or seventy times, and finally I removed it after it had been growing for fifteen years. I have frequently removed such tumors after they have been growing for nine or ten years. So this *may* be an ovarian tumor, or it *may* be a fibrous tumor. I should like very much to know which it is. If I should only pass an aspirating needle into it through

the vaginal or the abdominal walls, I might easily make the diagnosis; but if I did this you might, with reason, say that I was inexcusably rash, for an immediate decision of the matter is not necessary, and exposing the patient to danger to solve the problem would be unwarrantable. This woman is already thirty-seven years of age, and she will probably stop menstruating in three or four years, and then the tumor may cease growing, and she may live till seventy years of age without suffering any harm from its presence.

I talk about this so fully because I have seen so many bad results come from aspirating merely for the purpose of diagnosis. Even the smallest hypodermic needle has its dangers when used in this way. In case there was any necessity for making an accurate diagnosis, I would not hesitate to use the aspirator; but, where nothing is to be gained by the knowledge thus derived, I would avoid the risk.

Now I will tell this patient that the best thing for her is to go home and let herself alone. I will prescribe a bitter tonic, to improve her appetite and increase her strength, for she looks quite bloodless, and she has a small, feeble pulse; and, besides, I will put her on the syrup of the hypophosphites. Then I will tell her to wash out her vagina twice a day, so as to remove this secretion which keeps up a constant irritation in the vaginal canal; and that is all she needs. I would do nothing to favor the occurrence of pregnancy, because I think it is a highly desirable thing that she should not become pregnant, on account of the size and situation of this tumor, which would interfere with the proper development of the uterus.

It is a good rule to guide you always, when you are in doubt as to whether you had better risk any doubtful proceeding, to suppose your mother, or sister, or wife in the same position as the patient, and then do for her just what you would for one of them under corresponding circumstances. Now, I don't think, if this patient were a valued relative, you would plunge an aspirator into that tumor just to determine its character, when you could do nothing more to help her if you knew its true nature. I think there would be fewer accidents if men would remember and follow the rule I have just given you.

SUPRACRURAL LITHOTOMY.—At a meeting of the Société de Chirurgie ("Revue de chirurgie," Nov., 1883) M. Després reported that he had recently removed a phosphatic calculus, weighing 145 grammes, from the bladder of a young man, according to the method practiced by Roussel, the first French surgeon who performed the high operation. M. Després maintained that the peritonæum could be avoided with certainty during the procedure by taking the urachus as a guide, flanked by the two epigastric veins which ramify upon the vesical surface; and that safety in this respect was also insured by carrying the first incision along the linea alba to the extent of from seven to nine centimetres, according to the height of the pyramidalis muscle. In the case related, the patient made a good recovery. M. Sée observed that the indication furnished by the pyramidalis was not to be depended upon, as this muscle was differently inserted in different individuals, and was sometimes altogether wanting. M. Tillaux said that, according to his experience, the more the bladder was distended the larger would be the space left uninvested by peritonæum; the lowest part of the latter might thus be lifted as high as 3-5 centimetres above the pubes. Despite M. Després's opinion, therefore, the bladder should by all means be distended, and distended thoroughly, prior to the performance of hypogastric lithotomy. He totally rejected the guidance of the urachus as dangerous.

*Existing concurrently; an Ocular Demonstration upon the Living Subject of the Communicability of the Fluid in the Sac with that contained in the Ventricles of the Brain, by means of an Instrument of Precision; the Injection of Morton's Fluid, followed immediately by Coma and, four days subsequently, by Death, together with the Post-Mortem Appearances.**

By MILTON JOSIAH ROBERTS, M.D.,

PROFESSOR OF ORTHOPÆDIC SURGERY AND MECHANICAL THERAPEUTICS IN THE
NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING ORTHOPÆDIC SUR-
GEON TO THE CITY HOSPITALS ON RANDALL'S ISLAND, ETC.

THE case in question is a very interesting one, not only on account of its rather infrequent occurrence, but because of the ætiological, morphological, therapeutical, and prophylactical queries which are inevitably forced upon the mind of the scientific physician whenever he is consulted in regard to anomalies of this kind.

FIG. 1.

The child was about two months of age when I first saw him, and was suffering from a multiplicity of kindred

ailments having a prenatal origin. He was the offspring of a primipara nineteen years old. His paternal and maternal ancestors possessed an average degree of health—in fact, were declared to be unusually healthy. There was no knowledge of the existence of other instances of developmental abnormality in either branch of the family. The mother and father were not related.

About the first of April, 1883, the child came under my observation, the mother having brought it to the school for treatment. The case was transferred from the children's to the orthopædic department by Dr. J. S. McNutt.

Then, and for five months afterward, perhaps the most striking abnormality to be observed when the child was freed of its clothing was the presence of a broad, flat, sessile tumor situated in the mesial line of the back and involving the lower dorsal and lumbar regions.

A very good idea of its general conformation and the appearance of the child as a whole, as presented at that time, can be gained from an examination of Fig. 1, a reproduction, by the Ives process, of a photograph by Mr. James U. Stead, taken April 8, 1883.

The surface of the tumor was flat. Its edges, instead of overhanging the basal margin in the least degree, sloped by a gentle curve to meet the surrounding healthy parts. In outline, it was oblong and curvilinear, having very nearly the marginal conformation of a longitudinal section of an egg, with the broad end placed toward the head of the child. At two or three points, but confined to the face of the cephalic half of the tumor, were to be seen reddened areas of small extent, in the centers of which slight superficial ulceration existed. Between these reddened spots the surface presented a livid or ecchymotic appearance, which gradually faded away toward the sloping margins of the tumor, where its superficies had the semblance of healthy skin.

The slight ulcerations on the surface of the tumor and its peculiar coloring gave the appearance of extreme thinness to the walls in this part, the truth of which was confirmed by palpation. Over the caudal half of the sac and its entire circumferential margin the walls were much thicker and firmer to the touch, and the surface presented the appearance of normal skin.

Upon my first examination the tumor was ascertained to be nine and a half centimetres ($3\frac{1}{2}$ in.) in its longitudinal dimensions, or about one third the distance from the occiput to the coccyx. Its cephalic extremity was broad, and measured five centimetres (2 in.), while its caudal end was narrowed down to two and a half centimetres (1 in.).

Superficial palpation elicited undoubted fluctuation. Upon making deep digital pressure, the vertebral arches seemed to be entirely wanting. In order to test this point more fully, however, I ran my index-finger slowly and carefully down over the line of the spinous processes, and was enabled thereby to appreciate the individual segments of the spine as I proceeded, until I reached the cephalic margin of the tumor. Here

* Read before the New York Academy of Medicine, Section in Obstetrics and Diseases of Women and Children, January 24, 1884.

there was a sudden and entire absence of vertebral resistance, which condition proved to be continuous throughout the longitudinal extent of the tumor. It was now clear that I had to deal with a case where the arches of the vertebrae were absent in the lower dorsal and lumbar regions corresponding exactly with the cephalocaudal limitations of the tumor.

A careful inspection of the child's head at this time showed it to be unduly large, though it was probably not sufficiently so to have at once been recognized as pathological had nothing arisen to attract special attention to it. However, observation having been instituted, it was plain to be seen that its principal diameters—the occipito-frontal, the biparietal, and the trachelo-bregmatic—were in excess of their normal limits. The forehead was markedly prominent. Upon palpation, the membranous area at the junction of the sagittal with the coronal suture was found to be very tense, and far exceeded the limitations normal at the close of the second month of post-fetal existence. The sagittal suture was plainly felt to be open throughout its whole extent, and the posterior fontanelle was still unclosed. The coronal suture was also felt to be open for some distance on either side of the bregma.

It was evident that all these changes were due to distension of the cavities of the brain by an abnormal accumulation of fluid within them, the lesion suppositively being a chronic inflammation of the ependyma, familiarly known under the name of *chronic internal hydrocephalus*. Still more certain was the diagnosis made by the notation of the following facts:

Though the child's appetite was good most of the time, and he nursed regularly from a breast that supplied an abundance of milk, yet he was not so fat as babies ordinarily are. His muscles were flabby, and the general nutrition seriously impaired, the child presenting a somewhat starved appearance. There were no marked cerebral symptoms, such as frequent muscular twitchings, convulsions, etc. Nevertheless, such mild cerebral symptoms as failure to notice his surroundings, difficulty in attracting his attention to any particular object, want of animation, and an unnaturally mature facial expression were observed.

The eyes were affected by *double convergent strabismus*, most marked in the left member. The existence of this condition, in conjunction with chronic internal hydrocephalus, should probably be classed as a cerebral symptom. Apparently there was total loss of vision in the left eye. The pupils were moderately dilated, but responded slowly to light. Dr. George R. Elliott, who kindly made an ophthalmoscopic examination, reports that the veins of the retina in both eyes were considerably dilated and tortuous. There was an absence of pigment in the choroid in the vicinity of the left macula lutea, marking the site of a chronic retinitis. The remaining structures of the left eye and all those of the right appeared to be normal.

Another question now arose, viz., as to whether there was any connection between the fluid in the ventricles of the brain and that contained in the sac of the fluctuating tumor on the lower part of the child's back. An attempt was made to determine this point in the following manner:

With the tips of the first and second fingers of one hand placed over the anterior fontanelle, firm downward (central) pressure was made upon the tumor with the corresponding fingers of the other hand, and it was thought that a wave-impulse could be appreciated by the finger-tips over the bregma. The pressure momentarily interrupted the respiration, but the patient would soon catch his breath, take a deep inspiration, and follow it by a prolonged expiration, after which the breathing would become normal until pressure was again made. Though the perception of fluctuation by palpation was open to doubt, it was believed that a communication between the cerebral cavities and the interior of the sac did exist, and that the bond of union was the dilated central canal of the spinal cord. A probable diagnosis of *hydromyelia* was therefore made.

One more abnormality, *double talipes varus*, completes the list of ailments from which our little patient suffered at the time when I first saw him.

A few days subsequent to the preliminary examination which I have just detailed, I conceived the idea of making use of an instrument of precision for the final settlement of the one open question connected with the diagnosis in this case, viz.: as to the existence or non-existence of *hydromyelia*. It was evident that to rely upon tactile sensibility by placing the finger-tips over the spinal tumor and anterior fontanelle must in all cases be open to serious doubt as to its reliability. It had already been demonstrated in this case to be an imperfect test. The instrument which suggested itself to my mind was the *sphygmoscope* devised and perfected by my friend, Dr. F. P. Stephens (*vide* Fig. 2), whose original article, descriptive of its structure and uses, may be found in the "Medical Record" of September 11, 1880. Upon consultation with Dr. Stephens, he deemed it

FIG. 2.

FIG. 3.

advisable to modify the base of the instrument in order to secure a better adaptation of it to the surface of the fontanelle.

This was accomplished by removing the tube from the hard rubber base used for the pulse, and attaching to it the bell of a hand cupping-glass. Over the base of this a thin rubber diaphragm was stretched and secured, as shown in Fig. 3. The instrument, thus altered, was easily adjusted to any part of the bregma. A very small quantity of red-colored fluid in the base of the tube formed a liquid cork to the escape of the imprisoned air in the bell-shaped reservoir. It thus served as an exceedingly sensitive index, to point out, on a magnified scale, by its oscillatory movements, the slightest variation in the pressure on the diaphragm.

It was made clearly evident, from a few preliminary tests, that the movements of the head and those of the limbs, as well as the act of crying and the voluntary interference with the regularity of the respirations, on the part of the patient, were grave sources of error, falsifying the record of the index, and must be abolished during the experiment if any reliable data were to be gained by its performance. Accordingly, the infant was profoundly anesthetized. With the subject of the experiment rendered perfectly motionless, and the respiratory movements regular, Dr. Stephens proceeded. Placing himself comfortably, with supports under each arm so as to avoid all possible motion, he held the diaphragm of the sphygmoscope carefully against the anterior fontanelle, while he made pressure on the tumor as desired with the fingers of the other hand. In this position, the child motionless, the respiration regular, and the index at the bottom of the scale, firm downward pressure was made upon the sac. The index then steadily rose to the top of the scale, a distance of a hundred millimetres, and there remained until pressure was removed from the tumor. Though the pressure was suddenly taken off, the index did not fall quickly, but gradually sank to its former position at a little slower rate than it arose.

These observations were considered sufficient to place the diagnosis of hydrorrhachis in conjunction with chronic internal hydrocephalus beyond the possibility of a doubt. They were also believed to demonstrate that the fluid in the sac and dilated central canal of the spinal cord could not be forced through into the ventricles of the brain with sufficient rapidity to create a wave-impulse that could be appreciated by the unaided senses. Indeed, it was thought that to accomplish this in any case the dilatation of the central canal must be excessive and the opening into the ventricles unusually large. Hence the conclusion that in the sphygmoscope we have an instrument of diagnostic importance in many cases of hydrorrhachis. In these experiments Dr. Stephens was assisted by Dr. J. Leonard Corning, Dr. Elliott, and myself.

We have as yet only reached the threshold of a train of interesting questions suggested by this case, but I can only tarry long enough to briefly mention some of them.

First among these is, perhaps, the question of the frequency of occurrence of developmental abnormalities at birth. Our data upon this point are not very satisfactory, but I may say that, counting all external deviations from the normal as deformities, it has been estimated that these cases are met with once in three thousand births. Of course, in this reckoning no allowance is made for visceral malformations.

The ætiology of these disastrous sequences of the perpetuation of the human race is another point of interest which has always had charms for speculative, inquiring, and credulous minds. Of the causes which have been adduced in explanation of their occurrence, probably that of the influence of the maternal mind upon the developing embryo has received more support than all others put together. The sight of unwholesome objects, the witnessing of a tragedy, ungratified maternal longings for some article of food, are a few of the many causes cited by the laity and confirmed by the testimony of many members of the medical profession as capable of perverting the developmental processes. Professor William A. Hammond, in a masterly review of this whole subject of the influence of the maternal mind over the offspring during pregnancy, has expressed the opinion, regarding illustrative examples of this idea cited by him, that "the chances of these instances being due to coincidence are infinitesimally small." *

While freely admitting, in fact urging, that maternal mental influences bear a direct causative relation to the production of some prenatal deficiencies, I am equally positive in the opinion that this theory alone can not account for the occurrence of all the examples met with. The particular case under consideration could scarcely be cited in support of this theory. For, not only does the mother declare that she had no "presentiments," ungratified longings, accidents, etc., during the period of utero-gestation, but she did not even know of the existence of the spinal tumor or other defects until more than two weeks after the birth of the child. We must then search for other disturbing influences in order to offer a rational explanation of the manner in which some of these abnormal physical conditions are brought about. For this purpose let us review very briefly some of the metamorphoses of embryonic life pertinent to the case before us.

One of the very first signs of developmental advancement after the impregnation of the ovarian egg, its division into cleavage-masses (*segmentation*), the separation of the resulting embryogenic tissue into external (*epiblast*) and internal (*hypoblast*) layers, and the formation between these of an intermediate stratum (*mesoblast*), is the appearance of a linear depression on the surface of the blastoderm. From the substance of the mesoblast there grows up along each side of this primitive groove a ridge, which, in its uprising, pushes before it the superimposed epiblast. In the embryo it is normal that the groove thus formed should remain widely open from the time of its formation up to about the fifteenth day of utero-gestation. Shortly thereafter, however, and sometimes even as early as the twelfth day, the process of closure begins, and is first marked by the near approach of the lateral folds in the region of the neck. At a still later period, corresponding to the development attained in the child on the second day, these folds have completely coalesced along the median line so as to form a closed canal. The conversion of the "medullary groove" into the "medullary or neural canal" proceeds from the cephalic toward the caudal end of the embryo. From the inner surface of

* "Journal of Psychological Medicine," vol. ii, 1868.

this canal, throughout its whole extent, a growth of nervous tissue takes place, which ultimately forms the brain (*encephalon*) in the dilated end, and the spinal cord (*myelon*) in the attenuated part of the canal.

As will appear hereafter, it is of interest to note at this point that the whole of the canal is not at once occupied with nervous tissue, but that its lumen is gradually encroached upon with the advancing development of the embryo until about the end of the sixth month of uterine life, when the central canal of the spinal cord is no longer visible as such to the naked eye.

Simultaneously with the changes which have just been described, equally important formative processes have been in active operation elsewhere. A cartilaginous string, known as the notochord, or chorda dorsalis, has been developed along the line of the medullary canal, but immediately beneath it.

It would be interesting to follow closely the further histological differentiation of the embryonal units into their heterogeneous axial and appendicular sequences. Such a course, however, does not fall within the intended limits of my present remarks. Nor can I even attempt a detailed description of the intricate morphological changes incident to the development of the so-called primordial vertebrae, or protovertebral discs, and the reconstructive processes connected with the formation of the permanent spinal segments.

I wish only to state that, for the most part, the notochord appears to serve the function of a developmental guide-post in the construction of the spinal column; for it is around and at the sides of it that the bodies of the vertebrae are formed. From these the pedicles spring and extend upward upon either side of the medullary canal. The laminae, continuous with the pedicles, coalesce over the medullary canal, and are finally capped by the spinous processes.

The chondrification of the vertebral column in the human embryo begins about the sixth or seventh week. It progresses rapidly in the bodies of the vertebrae, but much more slowly in the arches, their coalescence by cartilage not being effected until about the close of the fourth month (Kölliker). Thus it is that the neural arch is formed and the spinal cord completely roofed in throughout its entire length.

The vertebral column, at first cartilaginous, early commences its transformation into bone. Ossific deposits primarily make their appearance in the laminae about the seventh week of prenatal life. A little later—about the eighth week—they are to be found in the middle of the cartilaginous vertebral bodies. It should be borne in mind that the process of ossification in the laminae does not occur in all of them at the same time; it is successional, and proceeds, as did the closure of the medullary groove, from the head, caudad. Not so with the bodies of the vertebrae. Here ossification begins in the middle of the column and proceeds in both directions simultaneously (Quain).

Though the commencement of bony deposits in the spinal column is at such an early period of fetal life, it is not, however, until about the thirtieth year of post-fetal life that the process of vertebral ossification is completed.

With these facts before us, it is plain to be seen that, in

the present instances, whatever caused a cessation of the development of the neural arch in the dorso-lumbar region as soon as the bodies of the vertebrae were formed must have exerted its influence at an exceedingly early period of embryonic life. It must, in fact, have been in active operation as early as the fifth week, probably before the mother suspected she was pregnant, and positively before she could have been at all certain of it. Again, the hydrorrhachis and the hydrocephalus may both be explained upon the supposition that the arrest or perversion of the growth of nervous tissue took place before the normal extent of encroachment upon the lumen of the medullary canal had been reached, thus leaving the central canal of the spinal cord and the ventricles of the brain abnormally large, intercommunicating and occupied by cerebro-spinal fluid.

Lastly, no error in refraction being found upon ophthalmoscopic examination, I think it probable that the double convergent strabismus in this case arose from undue pressure upon some part of the abducens, or sixth nerve, in consequence of the presence of an excessive amount of ventricular fluid. In like manner, pressure upon the lower end of the spinal cord, exerted by the fluid contained in the dilated central canal, may be cited in explanation of the occurrence of the double talipes varus. This latter opinion seems to be the more probable in the light of the fact that in some cases of spina bifida, where the patients have been born with their feet in a perfectly normal position, and remained so during several weeks or months of post-fœtal life, they have acquired talipes coincidently with the rapid enlargement of the spinal tumor, which ultimately took place.

Though the aetiology of developmental abnormalities is as yet wrapped in obscurity, sufficient reliable evidence has already been accumulated to warrant the conclusion that all of them can not be attributed to any one cause; and that, in the prosecution of our aetiological inquiries, we must be on the alert for evidences of primary defect in the sperm or ovum, or both, as well as for the influences, mental and physical, which may pervert the processes of histological differentiation that takes place after the union of the male and female elements.

In the treatment of this case, attention was first directed to the condition of spina bifida. The method which was adopted was that of the partial evacuation of the contents of the sac by means of an aspirator, followed by thorough compression. A gutta-percha pad was adapted to the tumor, and secured in position with a broad belt. At one end of the belt was sewed a tongue of rubber webbing, which, when the belt was applied, was passed through a buckle sewed to the other end of the belt, thus exerting any desired degree of elastic circumferential pressure. For the purpose of utilizing the force of gravity, the child was furnished with an upholstered wire cuirass, in which it could lie. This was so arranged that, when placed upon a level surface, the cephalic end was lower than that of the opposing end. The mother was also directed when handling the child to keep its head upon the same level with the body, or lower, as much of the time as possible. For a time the patient improved; the sac decreased in size, and its walls

were felt to be thicker. Fluid was withdrawn from the sac at intervals of three or four weeks, and the compression continued uninterruptedly for more than four months. On two occasions a galvanic current was passed through the tumor and its contents by introducing into it a needle, all but the point of which was covered with hard rubber, and applying the other electrode over an adjacent indifferent point on the body. This procedure did not appear to have much effect in exciting inflammatory action. On the occasion of the first application of galvanism, the respiratory and cardiac functions were very seriously interfered with, so that it was not long continued.

After a thorough trial in accordance with the above plan of treatment, finding my patient no better—in truth, on the decline—I determined upon the operation of excision of the sac. It was thought that this operation would even be less serious than that of injecting an irritating fluid into a sac freely opening into the dilated central canal of the spinal cord, and communicating, through it, with the ventricles of the brain.

Upon consultation, however, with Professor James L. Little, it was deemed inexpedient to open the sac, in view of the probable fatal issue of the case. The child's condition was now bad; he did not nurse well, was considerably emaciated, and had recently begun to have convulsions.

The flattering results reported in several quarters from the injection of Morton's fluid seemed to point to this as the only plan of treatment that promised any hope whatever, even of prolonged palliation.

The head of the patient was placed low, so as to avoid any sudden change in the intra-ventricular pressure upon the removal of fluid from the sac. With an aspirator I withdrew 20 c. c. of cerebro-spinal fluid, and began the slow hypodermic injection of the irritating fluid: Iodinii, gr. x; potassii iodidi, 3 ss.; glycerin., 3 j.

I had introduced only ten minims when, to my surprise, my little patient suddenly ceased breathing and the radial pulse became imperceptible. Efforts at resuscitation were immediately begun, which, after a half-hour's anxious and persistent efforts in the use of stimulants and artificial respiration, resulted in the re-establishment of pretty regular breathing, though the child did not regain consciousness. He remained comatose for four days, at the end of which time he died.

The post-mortem was made by Dr. Elliott, assisted by Dr. Roberts. Dr. Elliott's report of the findings is as follows:

INSPECTION.—Body is extremely emaciated; the anterior and posterior fontanelles and sutures adjoining are widely open.

In the dorso-lumbar region of the spinal column, in the mesial line, is an oval tumor, very tense to the touch and distinctly fluctuating.

Its covering varies much in thickness, being in places very thin and translucent, showing plainly the capillary blood-vessels; in other places there is considerable thickening, apparently the result of inflammatory exudation. The thickening is especially marked in the entire circumferential part of the tumor, where there is a thick band of tissue

grading into the sac-wall covering the superficies of the tumor on the one side, and into the healthy skin on the other. Over the surface of the swelling are to be seen cicatricial spots, the result, probably, of superficial ulceration.

Upon opening the sac, it was found to contain 30 c. c. of turbid fluid, which, when subjected to microscopical examination, showed red and white blood-cells and columnar epithelia. Chemical examination gave in addition the normal ingredients of cerebro-spinal fluid.

The inner wall of the sac appeared to the unaided eye like a serous surface with nerve fibers coursing over it. The base of the tumor rested upon the bodies and pedicles of the eleventh and twelfth dorsal and of all the lumbar vertebrae. Lying upon the bodies of the first, second, and third lumbar vertebrae and projecting into the cavity of the sac was found an oval-shaped growth of nervous tissue, the contour of which was identical with that of the tumor in question, but very much smaller. In the substance of this growth were found three different sites of former hemorrhage, each being the size of a pea.

At the upper or cephalic end of the sac there was an aggregation of nerve fibers, which immediately broke up, some of which coursed around the growth at the base of the tumor, traversed the sac-wall throughout its entire extent, and perforated it at its caudal end at various points; other fibers passed directly into the growth, in the substance of which they were lost. From the lower part and sides of the growth nerve fibers appeared to originate and traverse the lower part of the sac-wall, which they perforated similarly to those above mentioned.

Careful dissection at the cephalic end of the sac showed the walls in great part to be lined with the original membranes of the cord, it being possible to separate the pia mater from the dura for a considerable distance at the base and sides. On the sides, however, the pia mater grew very thin and attenuated, and it became impossible to trace it above the line of the transverse processes of the vertebrae. At the upper part of the tumor cavity the central canal, lying within the aggregation of nerve fibers above named, was distinctly visible, appearing to take origin from the dilated sac. The canal was one sixteenth of an inch in diameter. The macroscopic appearance at the level of the ninth dorsal vertebra, which was normally formed, was that of a tube within a tube with nerve tissue intervening, the external one being formed by the membranes of the cord, the inner, the dilated central canal.

Upon examination of the spinal column, the spinous processes, laminae, and posterior portion of the transverse processes of the eleventh and twelfth dorsal, and those of all the lumbar and sacral vertebrae, were found wanting. Permission to examine the cord above or to make a more complete autopsy could not be obtained.

In making a retrospective survey of a case like the foregoing, the query very naturally suggests itself, Could these embryonic defects have been prevented? Or, to make the question more general, Is it possible under any circumstances to prevent developmental deficiencies? This opens a very wide and inviting field for speculation and experimental research. The limits of this paper, however, only

permit me, in conclusion, to express the opinion that already sufficient facts have been carefully observed and recorded to make an affirmative answer to this question highly probable.

THE PRESENT STATUS OF ORTHOPÆDIC SURGERY.

By NEWTON M. SHAFFER, M.D.

TRACING the history of orthopædic surgery from the time of Andry to the present day, we notice that its more important progress has taken place within a very recent period. It will be further noted that America has made by far the most important contributions to, at least, the mechanical element in orthopædic surgery, and that the impetus given to the study of diseased joints and curved spines by American surgeons has influenced the treatment of these diseases and deformities throughout the entire world.

Whether it was Brodie or Harris that first used or pointed out the value of traction in joint disease, or whether the possibility of successfully treating Pott's disease by apparatus was first suggested by English or American surgeons, matters but little from a practical standpoint.

It will probably not be disputed that Dr. H. G. Davis, formerly of New York, conferred a great benefit upon humanity when he gave his perfected apparatus to the world, embodying the principles of traction as applied to joint disease; and, since his day, while various surgeons have from time to time modified and changed Davis's instruments, the Davis principle underlies all of them. His plain and simple directions as to the mechanical principles involved in treatment are followed, more or less in detail, by almost all who treat diseased spines and joints to-day.

Twenty-one years ago, when the writer began the study of orthopædic surgery, there was little to be proud of in its status in the city of New York. At that time a certain prominent surgeon, in speaking to the writer, not only discouraged the adoption of orthopædic surgery as a specialty but predicted that any one adopting it would fail and be called a blacksmith for his pains.

Forty years ago orthopædic surgery did not include joint and spinal disease, but only such deformities as club-foot, wry-neck, knock-knee, etc. Strabismus was classed as an orthopædic condition by Bigelow when he wrote his prize dissertation in 1845—about ten years before Davis gave to the profession his treatment of joint and spinal diseases. After Davis's time, those making any pretense to the treatment of deformities classed joint and spinal diseases as orthopædic; or, at least, their reputations have been due to successes not so much in the field of tenotomy as from mechanical and operative procedures in diseases and deformities of the joints and spine. It is, perhaps, in this latter field that Bauer, Sayre, and Taylor appear to the greatest advantage, and the teachings of these gentlemen, all more or less inspired by Davis, form the foundation of much of the orthopædic surgery practiced in the United States to-day; for, while all must concede the debt owed by orthopædic surgery to Dr. W. J. Little, of London, that eminent writer, the father of orthopædic surgery in Eng-

land, does not include articular disease in his treatises, and, without a full discussion of mechanical and operative treatment of joint disease, no treatise on orthopædic surgery can now be called complete.

It is not intended, however, to make this short note an historical review of orthopædic surgery; it is neither profitable nor necessary to raise points which may involve questions of priority. It is rather the aim of the writer to give a short sketch of what orthopædic surgery is to-day, and what it demands from those who enter upon its study and practice, for orthopædic surgery may now be ranked among the growing and necessary specialties—as a more useful one, indeed, than some which make greater pretensions.

In my lectures at the University Medical College and at the New York Orthopædic Dispensary and Hospital I have ventured to define orthopædic surgery as follows: "That department of general surgery which includes the mechanical and operative treatment of chronic and progressive deformities, for the proper treatment of which specially devised apparatus is necessary."

Whether, therefore, the condition be one of club-foot, joint disease, lateral curvature, or spinal caries, the indications are to be studied, and these indications are to be met from a pathological, anatomical, and mechanical standpoint. To do this the orthopædic surgeon must be fully informed upon general medicine and surgery, and must be prepared to prescribe his apparatus precisely as a general practitioner prescribes a remedy for disease.

In order to satisfactorily carry out the system of prescribing apparatus for deformities, the instrument-maker should be placed in the same category as the pharmacist, and should supply apparatus for deformities only upon a prescription—i. e., a carefully executed diagram of the apparatus needed. But how is an educated orthopædic surgeon to execute this plan? While orthopædic surgery has advanced to the dignity of a well-recognized place in general surgery, the facilities for filling a mechanical prescription are in some respects no better than they were fifty years ago. As a rule, the instrument-maker who now fills the prescription of the orthopædic or general surgeon is not unwilling to treat deformity himself, and it not infrequently occurs that he makes suggestions to the patients that are sent to him. There is, I regret to say, some excuse for this, for it has sometimes happened that the instrument-maker has a better idea of what is needed than the surgeon who sent the patient to him, for the reason that orthopædic surgery is not, as a rule, taught in our medical schools, and the generally lax way in which chronic deformities are referred to leaves the newly fledged graduate utterly unprepared to treat them, especially in a mechanical sense. Nor is it at all unusual for the instrument-maker to be called in a kind of a consultation by the surgeon, to devise some sort of apparatus to accomplish an ill-defined end in a given case of deformity or disease. Still further, there are scattered throughout the country various agents of the prominent instrument-making firms—druggists, for example, who prescribe for the most serious cases in orthopædic surgery and order an apparatus from a distance about which they know little or nothing, except that gained from the cata-

logues. The amount of deformity—not to mention incidental suffering and expense entailed by this system of ignorance and charlatanism—can not be estimated. The writer knows that in a certain city not far from New York an instrument-maker is called in by the surgeons of a certain hospital, and the patient is practically turned over to the mechanic after a diagnosis is made, as if there were something degrading and unprofessional in attending in detail to the mechanical department of orthopædic work.

But it requires education and a long systematic training to make a competent orthopædic surgeon; and more: it requires a peculiar adaptability to successfully prosecute the mechanical detail in any case of orthopædic surgery, even under the best auspices. The orthopædic surgeon should be able, as a matter of education, to make, if necessary, the apparatus which he needs. He should at least know *how* to make it; he should know more than his workman about the various grades of steel, the points where strength is necessary, where lightness may be tolerated without sacrifice to strength, etc.; and, indeed, unless one is willing to master such details and to become a mechanician himself, it is better that he should let orthopædic surgery alone. No man can be a scientific orthopedist, competent to give to his patients the skill which they have a right to demand, who does not become responsible for everything not directly pertaining to the manufacture of the instruments to be used. The day can not be very far distant when the truth of these statements will be recognized; and, while a more comprehensive course of instruction in orthopædic surgery will be demanded, the various public institutions will provide the means by which deformities can be properly cared for.

There seems to the writer to be no reason why the mechanical element of treatment should be ignored because it is so purely objective; nor can he imagine that a disease or a deformity essentially painless in its nature, though insidiously progressive in character, should be relegated to an uneducated class simply because death is not imminent. The pathological conditions existing in many cases involving deformity are very serious, and should not be placed in the hands of ignorant or designing men. They can not be successfully handled by even the general practitioner unless he has the time, the ability, the experience, and the patience to follow a case in detail for perhaps two or three years. Success such as ought to characterize orthopædic practice comes only through hard work, patient attention to detail, and a thorough mastery of mechanical surgery.

These matters are, I think, more thoroughly appreciated in New York than elsewhere in this country. When the writer was appointed orthopædic surgeon to St. Luke's Hospital, eleven years ago, it was with the distinct understanding that these principles were to underlie the orthopædic work, and the success of the movement there is greatly due to this provision.

In the New York Orthopædic Dispensary and Hospital there is, in direct connection with the institution, a fully equipped mechanical room in which four or five men are constantly employed making apparatus directly under the instructions of the surgeons; no apparatus is made without

a drawing, and careful measurements accompanied by actual outlines, when necessary, being given with every order; no repairs are made except by personal instruction of the surgeons, accompanied by drawings if necessary. The consequence is that cases are there treated with great satisfaction, and the instrument-makers have there become skilled workmen, some of whom have gone to the aid of orthopædic surgeons in other cities. It is a great pleasure to note in this connection that in another city steps have been taken to introduce the methods of the New York Orthopædic Dispensary into one of the most prominent hospitals and medical schools of the country. The Orthopædic Dispensary of the University Hospital in Philadelphia has, in connection with its service, a fully equipped shop, supplied with steam-power, where the apparatus used is made after the diagrams, and under the direction of the attending surgeon. This change can not but result in good, for reasons that must be apparent to all. It relegates the instrument-maker to his proper sphere, bringing him wholly under control of the surgeon, upon whom it fixes the entire responsibility for the conduct of his cases. No delays are incurred either in making new apparatus or in repairing old ones, and the patients are supplied with apparatus at first cost—an important item when one considers the enormous prices charged by instrument-makers for their apparatus. The fact is, that all hospitals should be similarly equipped with a complete orthopædic department. The expense is not great. Dr. A. Sidney Roberts, formerly an assistant surgeon to the New York Orthopædic Dispensary and Hospital, and through whose personal exertions the orthopædic shop of the University Hospital was organized, informs me that the entire cost of the same did not exceed \$2,000, which includes a building erected for the purpose, and that the shop is now nearly self-sustaining—actual cost of production only being charged to those patients who were able to pay it. This is certainly a good exhibit, and confirms our experience at the New York Orthopædic Dispensary. The great advantage it will confer upon the institution, the surgeons, and the patients, leads to the hope that other colleges and hospitals throughout the country may be led to adopt the same plan, and thus, while extending to a large class of sufferers all the benefits of a thorough, systematic, and scientific treatment, aid in placing orthopædic surgery in its proper status before the profession at large.

THE ETIOLOGY, PATHOLOGY, AND TREATMENT OF HÆMORRHOIDS.

By JOHN HARVEY GIRDNER, M.D.

THE last six to eight inches of the large intestine composes the rectum, and, like the remainder of the gut, is made up of four coats. If we remove a healthy rectum from a body recently dead and make a section through its walls in the long diameter of the gut, we shall find that the cut edges present the following characteristics: The most external of the four layers forming the wall is a serous membrane, derived from the peritonæum; the next layer we come to, passing inward, is the muscular, formed of both longitudinal and

circular fibers; the third is the cellular membrane, composed of connective tissue, showing in its midst the hæmorrhoidal vessels and nerves, and serving to connect the most internal or mucous layer with the muscular. The internal or lining membrane of the gut differs in no essentials from other mucous membranes so far as its histological anatomy is concerned. The mucous layer is, however, more abundant than any of the others; that is, if the mucous membrane be dissected from a segment of the gut of a known length, it will be found to be longer and wider when compared with the remaining layers from which it has just been removed and which it formerly fitted; in the normal condition this redundancy of the mucous layer of the rectum is compensated for by the former being thrown into folds, and these folds are both transverse and longitudinal, the latter especially in the neighborhood of the sphincter ani. Now, the interposition of the loose cellular tissue between the muscular and this mucous layer permits the latter to be thrown into folds, to be distended, and to slide or be rolled on the muscular coat with facility.

Thus constructed, this gut serves as the exit for the effete contents of the alimentary canal. Now, there are accumulations of fecal matter, large, irregular, hard masses, which lie for hours and days in the upper portion of the rectum just below the sigmoid flexure, awaiting the delayed signal to move on to the outer world. And as they lie in the gut they distend the mucous membrane at the point and press upon the submucous veins, thus more or less completely stopping the return of the blood from the hæmorrhoidal plexus and damming it back in heavy and increasing columns on the veins in the lower portion of the rectum and about the anus. By and by the signal comes for this mass to move, and the process of defecation is begun; by the vermicular motion of the gut, and the pressure of the superimposed viscera brought to bear by bearing-down efforts, this large, hard, irregular mass moves, slowly distending the gut to its fullest and pushing before it the folds of the mucous membrane, and also the blood in the submucous cellular tissue until it arrives near to the sphincter, when that muscle dilates and these accumulated folds of mucous membrane, distended with the blood which has been pressed into them from along the sides of the rectum, pass out of the orifice of the anus, followed by this mass of hardened feces streaked over with the blood from ruptures of small distended vessels along its course. Now the sphincter closes involuntarily and shuts out these tumors and effectually ligates their necks, and we have external piles, which are nothing but bags composed of mucous membrane which has been pushed out before fecal discharges, and filled with connective tissue and distended blood-vessels which have been pressed into them by the same cause from the submucous cellular tissue of the gut.

Just within the sphincter ani the rectum is somewhat dilated, and is much larger than in any other portion; and sometimes when the mass has reached this point there is room enough for it to pass over these folds of mucous membrane and accumulated blood, and then it passes out clear, leaving these tumors on the inside of the sphincter, and we then have internal piles. The ætiology and pathology of

external and internal piles are the same; they differ only in location, and in the fact that one is ligated by the sphincter ani and the other is not.

In an improperly made coat it sometimes happens that the cloth shrinks; this leaves the lining of the skirt too large, and the latter will then hang in a bag below the border of the skirt; this is exactly the condition of the mucous membrane in external piles. If we look at one of these external bags of mucous membrane which has only recently been formed, it will appear of a dark purplish color, and very moist on the surface from transudation of the water of the blood confined within. Cut this tumor open, and it is found to contain distended blood-vessels, either arteries or veins (nearly always the latter), often a nerve or two of considerable size, with a quantity of connective tissue.

If these tumors have existed for a long time, permanently hanging from the verge of the anus, they present a different appearance. Instead of dark purple, they are of a pale color externally, and often their surface is covered with fissures, small ulcers, and fibrous cicatricial thickenings. Cut one open, and the same pale color exists, except in the center of the tumor there is a spot of dark color, shading off to light yellow, and marking the point where a blood-vessel perished, the hæmoglobin of the blood thus staining the surrounding connective tissue. Sometimes the passage of feces causes a rupture of one of these recent tumors, with considerable hæmorrhage from its contained vessel; generally, however, the hæmorrhage is not great, only sufficient to streak the surface of the fecal mass. The depression and shock to the physical, mental, and moral systems in recent cases is sometimes enormous, and can not be accounted for by the amount of blood lost. As I said above, nerves are often found in these recent bags, dragged down like the blood-vessels from their proper places in the submucous cellular tissue, folded upon themselves in these bags, and pressed upon both by the sphincter ani and by the confined blood by which they are surrounded. Here is a clear explanation of this shock; indeed, it would be phenomenal were it otherwise.

How shall we cure our patient? What would we do with the lining of a coat-skirt which hung in a bag below the cloth? The rational thing to do would be to cut off the redundant part of the lining even with the cloth and stitch it to the edge of the same. But we can not do that here, owing to the presence of blood-vessels which, if we cut, might cause dangerous hæmorrhage; we first, then, cut the tumor as near off as we dare, and ligate the remainder with the vessels contained. The ligature, then, first, last, and always. There is one other method, I am informed, which is practiced extensively by a quack in this city, and respectable members of the regular profession have also recommended it, viz.: the injection of these blood-tumors with a solution of carbolic acid or other coagulating substance. However favorable statistics can be shown of the results of this treatment, I do not hesitate to condemn it as exceedingly dangerous, and a man not ignorant of the pathology and anatomical relations of the tumor he deals with is guilty of unnecessarily exposing his patient's life and health by thus throwing a coagulating solution directly

into the circulation. It has been suggested that if a clot should break loose from these injected tumors it would be arrested in the liver, since the hæmorrhoidal veins empty into the portal circulation, and, it being a carbolized clot, would cause no abscess or harm of any kind in that organ, thus making the liver a kind of strainer to clean the clots out of the blood before it goes to the brain or other vital organ; but the hæmorrhoidal veins connect directly with the general circulation by inoculation with branches of the internal iliac, hence there is nothing to prevent a clot which had broken loose from one of these coagula formed by the injection from entering directly into the general circulation and plugging up an artery in the brain, or some other vital organ, which might at once prove fatal.

I do not wish to appear to overstate the case, but recent examination of the anatomy and pathology of the parts under consideration has so impressed me with the danger of these injections that I am earnest in giving it my condemnation.

Book Notices.

BOOKS AND PAMPHLETS RECEIVED.

A Treatise on Pharmacy: designed as a Text-book for the Student, and as a Guide for the Physician and Pharmacist. Containing the Official and many Unofficial Formulas, and Numerous Examples of Extemporaneous Prescriptions. By Edward Parrish, late Professor of Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy, etc. Fifth Edition, enlarged and thoroughly revised. By Thomas S. Wiegand, Graduate of the Philadelphia College of Pharmacy. With Two Hundred and Fifty-six Illustrations. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xxiv-17 to 1090, inclusive.

A Manual of Practical Hygiene. By Edmund A. Parkes, M.D., F.R.S., etc. Edited by F. S. B. François De Chaumont, M.D., F.R.S., etc. Sixth Edition, with an Appendix, giving the American Practice in Matters relating to Hygiene, prepared under the direction of Frederick N. Owen, Civil and Sanitary Engineer. Vol. II. New York: William Wood & Co., 1883. Pp. vii-556. [Wood's Library of Standard Medical Authors.]

Fat and Blood: an Essay on the Treatment of Certain Forms of Neurasthenia and Hysteria. By S. Weir Mitchell, M.D., etc. Third Edition, revised, with Additions. Philadelphia: J. B. Lippincott & Co., 1884. Pp. 164. [Price, \$1.50.]

Woman's Work in the Field of Medicine. College of Midwifery of the City of New York. Pp. 54.

Annual Report of the National Board of Health, for the Year ending June 30, 1883. Pp. 102.

Proceedings of the American Society of Microscopists, Sixth Annual Meeting, 1883.

Head Injuries accompanied by Paralysis. A Clinical Lecture delivered at the Bellevue Hospital, by Frederic S. Dennis, M.D., etc. [Reprint from the "Medical News."]

Hysteria: a Study in Psychology. By James Hendrie Lloyd, A.M., M.D., etc. [Reprint from the "Journal of Nervous and Mental Disease."]

The Relation of Dairy Products to Disease. By Hugh Hamilton, M.D., Harrisburg, Pa. [Reprint from the "Report of the Pennsylvania Board of Agriculture."]

Some Recent Progress in Diseases of the Nervous System.

By Talbot Jones, M.D., St. Paul, Minn. [Reprint from the "Alienist and Neurologist."]

Twentieth Annual Report of the New York Society for the Relief of the Ruptured and Crippled.

Fourteenth Annual Report of the Manhattan Eye and Ear Hospital.

The Australasian Medical Directory and Hand-Book. Edited and compiled by Ludwig Bruck. Sidney: "Australasian Medical Gazette" Office, 1883.

Transactions of the American Gynecological Society. Vol. VIII. For the year 1883. New York: D. Appleton & Co., 1884. Pp. 276.

Quarantine. By Walter Wyman, M.D., Surgeon United States Marine Hospital Service. [Reprint from the Report of the Maryland State Board of Health.]

Announcement of the New York Post-Graduate Medical School. Sessions of 1883-'84.

THE ETIOLOGY AND NATURE OF ZONA.—Erb's theory bearing upon these points, which has recently found an advocate in Landouzy, is explained and enforced by Henry Barth, in "L'Union médicale," November 10, 1883. According to Erb, zona is merely the local manifestation of a constitutional malady, derived from an external cause—i. e., the deposition of an infectious germ. This conception, however, applies only to the so-called *spontaneous* zona. It has nothing to do with the *secondary* and *traumatic* forms of the complaint, which, if the theory be accepted, must be regarded as differing essentially from genuine herpes zoster. The facts and arguments relied upon in support of this view may be briefly stated as follows: Spontaneous zona is a disease which, in the vast majority of cases, occurs but once in the same individual. This fact can only be explained by supposing that the organism is so modified by the morbid process as to be incapable of again developing the specific germ. This is what undoubtedly takes place in the case of whooping-cough, of mumps, and of all the other contagious disorders that occur only once, and furnishes a reason why zona should be regarded as of like origin with these. Besides, it is a mistake to suppose that the manifestations of zona are exclusively local. On close observation, the eruption is often found to be preceded by unmistakable constitutional symptoms—sometimes even by well-marked fever, which may last for three or four days. Again, all authors admit that zona is exceedingly apt to become epidemic, especially in large hospitals devoted to cutaneous maladies—a circumstance never hitherto intelligibly accounted for, but which Landouzy attributes to the prevalence of atmospheric conditions favorable to the ripening of the specific germ. The circumstance that the eruption is usually limited to a region supplied by one or more ramifications of a particular nerve does not conflict with the theory under consideration, since the same is true of many specific and constitutional affections, such as parotitis and whooping-cough. Neither can any valid objection be based on the pathological changes which have been observed in this disease. These changes undoubtedly show that the eruption is dependent upon an irritation of the spinal ganglia, but this irritation itself proceeds from an elective influence exerted by the specific germ after it has found its way into the system. In other words, spontaneous zona is essentially a morbid force which has settled upon the spinal ganglia, just as mumps is a morbid force which has settled upon the parotid gland; and the cutaneous symptoms are simply an indirect consequence of trophic disturbance due to an irritation of the nerve-elements. In this way we may account for the non-inoculability of zona, which would be inexplicable if the herpetic vesicles, like the pustules of small-pox and cow-pox, were caused by the elimination of a morbid product.

M. Barth concludes as follows: "These positions, to be sure, are hypothetical, but they rest upon positive facts, and must be admitted to merit our serious attention. Whether destined or not to be finally accepted, one good end will certainly have been gained by their discussion, if it shall serve to establish the distinction, which it is indispensable to observe in considering such questions, between the pathogenic and the ætiological standpoints."

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JAN. 26, 1884.

M. PAUL BERT.

It is much to be regretted that the opinions of medical men sometimes seem to have caught their tone from the clink of coin. It is humiliating to reflect that medical testimony in courts of justice is at times given in conformity rather to employers' preferences than to the strictly scientific interpretation of facts. That these dishonorable exhibitions do take place, it can not be denied. We are inclined to believe, however, that they are by no means so common as is generally supposed, and it seems quite certain that, when they actually do occur, they for the most part implicate those who are already of unsavory repute. Unquestionably, it is extremely rare for a member of the medical profession of so exalted a station as M. Paul Bert to find himself in a position where a charge of improper motives can be brought against him with any show of probability.

It looks very much as if M. Bert had laid himself open to the accusation, however. So long as the suggestion came only from this country, where self-interest may be alleged to color our interpretation of his course on the trichiniasis question in the French Legislature, it might not have quite force enough to put him seriously on the defensive; but now it comes from his own countrymen, from the recognized exponents of medical thought in France. In a telling editorial article, the "*Progrès médical*" riddles his argument, and, while not specifically charging him with subservience to improper influences, brings him plump against a dilemma one horn of which is ready to prick the bubble of his scientific ability, while the other bids fair to pin him to a conviction of disingenuousness.

At first we supposed that M. Bert had simply been over-zealous in advocating an opinion which, however at variance with the views of those more capable than himself of knowing the truth in the matter, had really something tangible to support it, and could, perhaps, be backed up by facts that it would be difficult to break the force of at once. But what are the facts? Contrary to the general impression in France, M. Bert suggests that trichiniasis is really not uncommon in that country, and he accounts for the error of those who think differently by maintaining, in substance, that the disease often passes unrecognized, being taken for typhoid fever. Now, we all know that the mistake is liable to be made in individual instances, but it is difficult to understand how a man of any pretension to a logical mind could seriously assert that it was constantly being made on a large scale—on such a scale, indeed, that a disease thought by the whole medical profession to occur seldom or never in France was really common. What a reflection on the diagnostic powers of his countrymen! Year after year they go on mistaking trichiniasis for typhoid fever! Elsewhere errors of this

kind are found out, at least in a few instances; but never by any chance in France! Apart from these reflections, is M. Bert ready to admit that the mortality of supposed typhoid fever is as great in France as it assuredly would be if any considerable proportion of the cases reported were really cases of trichiniasis? Manifestly, either typhoid fever is most murderous in France, or else our French brethren cure their trichinous patients as such patients are cured nowhere in any other part of the world—and, moreover, without knowing what they are achieving. What a blessing it would be for a country really stricken with trichiniasis if the French treatment for typhoid fever were only known there!

It appears that M. Bert is very solicitous for the working class. It will not do, he says, to give them unwholesome food simply because it is cheap. This proposition is, of course, a truism; but to hold it up as representing the facts in the question at issue, and that, too, without evidence enough to turn the heads of an ordinary coroner's jury, argues either a degree of fatuity fatal to his pretensions both as a statesman and as a man of science, or else a spirit that will inevitably consign him to the list of demagogues. He has nothing to oppose to M. Brouardel and M. Grancher's report, he does not contest the Andalusian origin of the outbreak in Malaga, he is silent in regard to Virchow's statement as to the non-occurrence of trichiniasis of American origin in Germany; he deals in nothing but his own assertions. We are told that he was eloquent on the occasion, and that his eloquence was such that the Minister of Commerce forgot to bring M. Brouardel and M. Grancher's official report to the attention of the Chamber, although he is said to have had it in his pocket at the time. This eloquence may be presumed to have consisted chiefly in vehemence, a quality that it is generally safest to smother.

THE PHARMACOPEIA AS A LEGAL STANDARD.

We are not aware that legislative enactment has formally declared in many of the States that the pharmacopeia shall be considered the standard to which all medical preparations bearing the titles given in that work shall conform. It is to be assumed, however, that, in the absence of anything expressed to the contrary, every purchase of such preparations implies the supposition on the part of the buyer that the article conveyed is of the composition and strength directed in the pharmacopeia. When a man buys a quantity of tincture of opium, he expects to get, not merely *some* solution of the active principles of opium in alcohol, but precisely *the* solution designated by that name in the pharmacopeia. So, too, when a prescription is filled, the prescriber's intention and just expectation are defeated if any ingredient differs from what that ingredient is commonly understood to be—if, in the case of an official preparation, it differs from the strength and composition laid down in the pharmacopeia.

In those States where the statutes do not require the strict conformity of drugs to the pharmacopeial standard, it may nevertheless come to be established by judicial decisions that the State intends to enforce such conformity; and decisions to that purpose are all the more likely to be given, it may be sup-

posed, if prosecutions in other States prove successful. It is on account of this moral effect, therefore, quite as much as in the interest of fair-dealing in Massachusetts, that the recent spirit shown by the Board of Health, Lunacy, and Charity of that State in dealing with a number of manufacturing pharmacists of Boston, and the board's success in the prosecutions involved, must be viewed with satisfaction. Not the least gratifying feature of the matter is the fact that the parties who were proceeded against are now reported to have come to the conclusion that it is best for them to pay the fines imposed, rather than contest the matter further, as it seems to have been their first intention to do. They have certainly chosen the wiser part, for their business would most surely have suffered had the profession come to understand that they persisted in defying the authority of the board, and, as a natural inference, that they meant to keep on making and selling inferior preparations.

We are not informed whether or not they have also given up the policy, said to have been resolved upon, of gaining their point in the future by plotting a reconstitution of the board, procuring the appointment of a board more pliant than the one with which they now have to deal. If they have really ever entertained such an intention, it will be well for them not only to refrain from attempting to carry it out, but also to take good care that proof is given of their having renounced it; otherwise, the medical profession will be apt to regard them as persons in whose productions it can no longer feel full confidence. Let this happen to them, and there will be nothing left for them but the nostrum trade.

The Massachusetts board is well entitled to the thanks of the profession throughout the country for the energy it has shown in this matter. As a general thing, there has been a feeling of confidence in drugs of American manufacture, and, as nothing could so surely undermine that feeling as the successful opposition of inculpated men to the operation of the law, so nothing could more strengthen it than their exposure and punishment.

MINOR PARAGRAPHS.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

BESIDES the papers read and the discussions held at the recent meeting of the American Public Health Association, a summary of which we gave our readers at the time, action was taken, in the form of resolutions, intended to advise Congress as to certain legislation considered of importance from a sanitary point of view. These resolutions have now been laid before Congress. One of them urges the advisability of providing for the scientific investigation of the causes of diseases and of the means for their prevention. Another calls attention to the need of devising legislation for the purpose of checking the immigration of insane paupers and criminals. Still another favors the re-enactment of the law of June 2, 1879, to guard against the introduction of infectious diseases.

FORBEARANCE TOWARD PATIENTS.

PATIENTS sometimes fail to carry out to the letter the wholesome injunctions of the code of ethics in regard to their duties toward their medical attendants—for the very good reason that, as a rule, they are wholly ignorant of the code. It happens

occasionally that their conduct is very aggravating, but so strong is the feeling of the necessity of forbearance bred in every regularly trained medical man that it is among the rarest of occurrences for resentment to be shown. No provocation coming from a sick person should be allowed to lead to any show of anger, much less to a blow. We regret to say that a member of the house staff of the Connecticut State Hospital at New Haven so far forgot his decorum recently as to strike a patient, and the patient was a woman. The hospital authorities discharged the young gentleman in dishonor, although the medical board had expressed the opinion that a severe reprimand would be sufficient. It would be hard to show that his punishment was too severe, but it does seem as if there must have been some mitigating circumstances.

THE TRICHINIASIS QUESTION IN CONGRESS.

ALTHOUGH there would be no lack of pretexts for retaliatory legislation founded upon the action of France and Germany in regard to American pork, it seems likely now that moderation will prevail for a time at least. Mr. Dunn, of Arkansas, a member of the Congressional Committee on Commerce, is reported to have said recently that it would be well, he thought—and in so saying he is understood to have shown the feeling of the committee—to do no more at present than take measures for the systematic inspection of our pork, both for the protection of our own people and to destroy the pretext on which the foreign governments concerned base their action. At the same time, he hints that, while the action of the committee will be deliberate, it will be none the less efficacious.

THE "JOURNAL OF CUTANEOUS AND VENEREAL DISEASES."

THIS journal, which was first issued in October, 1882, has now reached the completion of the first volume, including the October, November, and December numbers for 1882, and the twelve monthly numbers for 1883. We have received a bound copy of the volume, the appearance of which is very pleasing. Several months ago we remarked upon the creditable character of the dermatological literature that had emanated from America during the past fifteen years, and it is no more than simple justice to say now that the "Journal of Cutaneous and Venereal Diseases" is doing effective work in keeping that literature up to the standard.

THE MEDICAL SECTS AND THE PUBLIC SERVICE.

A BILL has been introduced into the Senate "to secure to the medical profession equal rights in the service of the United States," and providing that graduates of all legally chartered medical colleges shall be eligible to appointment in the medical corps of the army and navy, etc. Any such action on the part of Congress as this bill implies will prove as inoperative as it is unnecessary, unless, indeed, Congress abolishes the safeguard of the entrance examination.

NEWS ITEMS.

THE CARTWRIGHT LECTURES of the Alumni Association of the College of Physicians and Surgeons will be delivered by Professor Burt G. Wilder, M. D., of Cornell University, in the hall of the Young Men's Christian Association, corner of Fourth Avenue and Twenty-third Street, on the evenings of Saturday, February 2d, Monday, February 4th, and Wednesday, February 6th. *General subject:* Methods of Studying the Brain. (*February 2d:* Limitations of the subject to macroscopic encephalic morphology; methods of regarding the brain based upon its

condition in embryos and amphibia. *February 4th*: Methods of preserving and examining the brain. *February 6th*: Methods of figuring and describing the brain.)

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 22, 1884:

DISEASES.	Week ending Jan. 15.		Week ending Jan. 22.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	3	0
Typhoid Fever.....	5	2	7	3
Scarlet Fever.....	81	14	67	9
Cerebro-spinal meningitis....	4	4	5	5
Measles.....	52	6	40	4
Diphtheria.....	33	9	36	16
Yellow Fever.....	1	1	0	0

THE MARINE HOSPITAL SYSTEM.—The Senate Committee on Commerce is reported to have acted favorably on an amendment to the shipping bill providing for the abolition of the present system of supporting the marine hospitals by a tax on sailors, and throwing the expense directly on the Government.

THE INDISCRIMINATE SALE OF POISONS is in one respect unrestrained. We allude to poisons for the destruction of vermin. The danger of this laxity was lately shown by the serious poisoning of a family in Louisville by a preparation known as "Rough on Rats."

FAILURE OF A MEDICAL PUBLISHER.—Dr. Edward J. Bermingham, who has been doing a medical publishing business in Union Square, under the firm name of Bermingham & Co., is reported to have made an assignment to Frederick S. Lyons.

THE TRICHINIASIS QUESTION IN CINCINNATI.—The Chamber of Commerce of Cincinnati is said to have voted to memorialize Congress to take prompt retaliatory measures in regard to the prohibition of the importation of American pork into France and Germany.

THE HOSPITAL SATURDAY AND SUNDAY ASSOCIATION.—Up to last Monday, the amount received was \$40,082.03. The books will be kept open until February 15th.

THE NORTHWESTERN MEDICAL COLLEGE.—The secretary of the faculty, Dr. J. P. Chesney, informs us that the Missouri State Board of Health has decided to recognize the diplomas of the college.

THE HARTFORD HOSPITAL.—It appears from the annual report of the Executive Committee that 817 patients were treated during the past year, a daily average of 94. The work of the training school for nurses is said to have been highly satisfactory. Nine pupils were graduated during the year. The new wing, designed for the better accommodation of the pupils in the training school, and for a lying-in ward, is not yet completed, and it is estimated that about \$16,000 more will be needed to finish it.

THE NEW MEDICAL FACULTY AT PRAGUE.—The medical faculty of the new national university at Prague is to be constituted as follows: Descriptive anatomy, Dr. Steffal; pathological anatomy, Dr. Ilava, formerly Klebs's assistant; general pathology, Dr. Spina, of Vienna; physiological chemistry, Dr. Horbaczewski, of Vienna; physiology, Dr. Fomsa, of Kiev; clinical medicine, Dr. Eiselt; surgery, Dr. Veisz; syphilography and dermatology, Dr. Amosky; ophthalmology, Dr. Schobel; obstetrics, Dr. Streng.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 12, 1884, to January 13, 1884:*

BREWSTER, W. B., First Lieutenant and Assistant Surgeon. Resignation accepted by the President, to take effect February 7, 1884. S. O. 10, A. G. O., January 12, 1884.

MARINE HOSPITAL SERVICE.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service—October 1, 1883, to December 31, 1883:*

BAILLACHE, P. H., Surgeon. Relieved from duty at Cape Charles Quarantine Station, October 13, 1883. Detailed as member of board to examine candidate for promotion, October 30, 1883. Granted leave of absence for thirty days, November 27, 1883.

HUTTON, W. H. H., Surgeon. Granted leave of absence for twenty days, October 1, 1883.

WYMAN, WALTER, Surgeon. Detailed as member of board to examine candidate for promotion, October 30, 1883. To proceed to Norfolk, Va., to investigate the conduct of the Service at that port, December 31, 1883.

LONG, W. H., Surgeon. Leave of absence extended ten days, October 26, 1883.

MURRAY, R. D., Surgeon. To proceed to Ship Island Quarantine Station, October 17, 1883. To inspect sites for quarantine stations, November 30, 1883. Granted leave of absence for twenty days, December 18, 1883.

SMITH, HENRY, Surgeon. Granted leave of absence for twenty-five days on account of sickness, October 13, 1883. Relieved from duty at Norfolk, Va., October 17, 1883. To report to Surgeon Sawtelle, at New York, for temporary duty, November 27, 1883. Relieved from temporary duty at New York and placed on waiting orders, December 31, 1883.

FISHER, J. C., Passed Assistant Surgeon. When relieved by Assistant Surgeon Banks, to proceed to New York for duty, October 29, 1883. Granted leave of absence for thirty days, November 28, 1883.

GOLDSBOROUGH, C. B., Passed Assistant Surgeon. Granted leaves of absence for thirty-two days on account of sickness, October 12, October 20, and November 1, 1883.

IRWIN, FAIRFAX, Passed Assistant Surgeon. To proceed to Norfolk, Va., and assume charge of the Service, relieving Assistant Surgeon Glennan, October 16, 1883.

MEAD, F. W., Passed Assistant Surgeon. To proceed to Portland, Oregon, inspect the Service, and report the condition of Assistant Surgeon Devan, December 5, 1883. To return to station, Port Townsend, W. T., December 18, 1883.

COOKE, H. P., Passed Assistant Surgeon. To proceed to Charleston, S. C., for duty, November 27, 1883.

BANKS, C. E., Assistant Surgeon. Detailed for temporary duty at Georgetown, D. C., October 11, 1883. Granted leave of absence for thirty days, October 12, 1883.

BENNETT, P. H., Assistant Surgeon. Placed on waiting orders, December 15, 1883. Granted leave of absence for thirty days, December 22, 1883. Upon expiration of leave of absence to proceed to Detroit, Mich., for duty, December 29, 1883.

PECKHAM, C. T., Assistant Surgeon. To proceed to Wilmington, N. C., and assume charge of the Service, relieving Past Assistant Surgeon Irwin, October 16, 1883.

DEVAN, S. C., Assistant Surgeon. Granted leaves of absence for ninety-five days, on account of injury and sickness resulting therefrom, November 15, December 5 and 22, 1883.

BEVAN, A. D., Assistant Surgeon. To proceed to Portland, Oregon, and assume charge of the Service, December 29, 1883.

GLENNAN, A. H., Assistant Surgeon. To proceed to New Orleans, La., for duty, October 17, 1883.

WASDIN, EUGENE, Assistant Surgeon. To proceed to Mobile, Ala., for temporary duty, October 11, 1883. To proceed to Galveston, Texas, for temporary duty, November 17, 1883.

Promotions.

BENSON, J. A., Passed Assistant Surgeon. Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from October 1, 1883. October 4, 1883.

BANKS, C. E., Passed Assistant Surgeon. Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from November 1, 1883. November 6, 1883.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, January 28th*: Medical Society of the County of New York.

Tuesday, January 29th: New York Dermatological Society (private); New York Surgical Society (private); Medical Society of the County of Onondaga, N. Y.; Jersey City Pathological Society.

Wednesday, January 30th: Auburn (N. Y.) City Medical Association; Medical Society of the County of Gloucester, N. J.

Friday, February 1st: Practitioners' Society (private).

OBITUARY NOTES.

MAGNUS M. LEWIS, M.D., of ALEXANDRIA, VA.—Dr. Lewis died on Sunday, the 20th inst., in his sixtieth year. He was born in Jefferson Co., Va., February 8, 1824, and received his preliminary education in the University of Virginia, where he also took the medical course, but was graduated from Jefferson Medical College, Philadelphia, in 1847. During the civil war he entered the Confederate army as Regimental Surgeon, and passed through the grades of Brigade Surgeon and Division Surgeon up to that of Medical Director, gaining considerable repute as a surgeon. He was a member of the Alexandria Medical Society, the Virginia State Medical Society, and the American Medical Association.

JAMES MOORHEAD, M.D., died on Saturday last at his residence, No. 256 East Thirty-third Street, New York. He was born in County Fermanagh, in the north of Ireland, where he received a classical education, and was graduated from Bellevue Hospital Medical College in 1863. He had an extensive practice, which was to a great degree among the poorer classes, by whom he was much respected. He was a member of the Medical Society of the County of New York, and had been for several years connected with the Board of Health.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

A STATED meeting was held January 8, 1884, ROBERT F. WEIR, M.D., President, in the chair.

MULTIPLE INCISIONS FOR CIRCUMSCRIBED CONTRACTION.—Dr. A. C. POST presented a boy who had received an injury of the palmar surface of the ring-finger of the left hand, the result of which was that the finger was bent at an angle of about 70° or 80°. He operated for the deformity by making a series of transverse incisions, perhaps ten or twelve in number, and subsequently dressing the wounds with subnitrate of bismuth and

applying a metallic splint. The case illustrated the benefit of multiple instead of single incisions.

COMPOUND FRACTURE OF THE HUMERUS, INVOLVING THE SHOULDER JOINT.—Dr. L. A. STIMSON presented a man, thirty-five years of age, who fell two stories, striking his arm, while on the way down, upon a railing, and producing a compound fracture of the upper end of the humerus, communicating largely with the shoulder joint, the wound extending from the coracoid process across the upper part of the arm. The wound was washed with a bichloride solution, one to two thousand, partly closed by sutures, two drainage-tubes were inserted, and antiseptic gauze was applied. The interest in the case was confined to the plaster dressing which was used. It was a combination of plaster dressing upon the arm and a plaster jacket upon the body, united by three iron cross-pieces, which held them so firmly that the patient could be moved or turned in any direction without producing pain. Rapid recovery took place with a movable joint.

SPONTANEOUS DISLOCATION OF THE HIP JOINT OCCURRING IN THE COURSE OF ACUTE ARTICULAR RHEUMATISM.—Dr. STIMSON also presented a woman, thirty-seven years of age, who had an attack of rheumatism in December, 1882. The history of the attack was obscure, but the patient said that many joints were involved, that she remained ill for a long time, and that the deformity occurred as early, at least, as the following April. She finally came to Bellevue Hospital last summer, where Dr. Stimson saw her first in the month of September, and recognized a dislocation of the right hip joint backward upon the ilium. The interest of the case was partly in the rarity of the occurrence, and also in the facility with which the lesion might be overlooked. The subject had been recently written upon by French surgeons, and he had nothing to add except to say that the symptom of sudden cessation of pain, sometimes noted at the moment the dislocation occurred, did not appear to have been present in this case.

EXSECTION OF THE WRIST JOINT.—Dr. A. G. GERSTER presented a patient upon whom he performed excision of the wrist joint November 5, 1883. The patient, a woman thirty years old, had had a severe attack of acute articular rheumatism, which involved nearly every joint of the body, all of which regained their functional ability except the wrist joint, which remained swollen, hot, and stiff. The patient was treated in the medical wards by the use of internal remedies, counter-irritation, and local applications, but without much improvement, and finally she was transferred to the surgical side, where Dr. Gerster found very extensive agglutination of the flexor and extensor tendons in their sheaths, and the hand resembled more a flipper than a hand. With reference to the joint proper, he found evidence of disease of the radio-carpal articulation. The condition of the carpus proper, however, made him anticipate that the carpal joint proper was not involved. On the inner side, moreover, at a point corresponding to the radial artery, a reddened spot appeared on the skin, showing that perforation was imminent. He proposed to the patient to have the joint examined, and, if the condition were such as demanded it, to finally perform excision. She consented to the operation, and Dr. Gerster made a lateral incision upon the ulnar side, intending first to remove the ulna and thereby increase the facility with which the radius could be removed. In other words, he performed Lister's operation. Having excised the carpal ends of the radius and ulna, the wound was closed and capillary drainage established by the introduction of a few strands of catgut. A bichloride solution was applied, and sufficient support was given by the antiseptic dressing to obviate the necessity of using a splint. No fever whatever followed the operation, and on the tenth day, when the dressing was changed, it

was found that primary union of the wound had taken place. The small strips of iodoform gauze placed immediately over the wound were simply colored with blood, but the remainder of the dressing was perfectly clean. Active and passive motion were begun on the second day after the removal of the dressings, and had been continued. The flail-like mobility was considerable after the operation, but this had been improved, and the patient was now able to extend and flex the hand without support; the mobility of the fingers had also improved very much in consequence of careful orthopaedic treatment. Dr. Gerster expected that she would have a tolerably useful hand. The carpal ends of the radius and ulna to a distance of two inches were removed, and the rest of the carpus was allowed to remain. The ends of the radius and ulna which were removed were devoid of cartilage, and the joint contained a small quantity of sero-cheesy pus. The capsule of the joint was infiltrated and thickened; the inner aspect of it was red, giving the peculiar velvety appearance seen in joint disease; and the perforation mentioned as being imminent on the volar side of the joint was found to be due to the burrowing of pus. No examination was made for the tubercle bacillus.

Dr. Post thought it very unusual for such extensive disease of the joint to occur without involving the carpus.

REMOVAL OF THE SUPERIOR MAXILLA: DIVISION OF THE FIFTH NERVE AND MECKEL'S GANGLION BY CARNOCHAN'S OPERATION.—Dr. J. W. HOWE presented a patient with the following history: Her name was Freidman, aged forty-five, a native of Hungary. Twelve years ago, without any appreciable cause, she felt a pain in the region of the lower bicuspid tooth on the right side. The pain gradually increased in frequency and in intensity. It was usually aggravated by exposure to cold and heat. The paroxysms continued up to within three years of her admission to the hospital, varying little in severity. The inferior maxilla was first involved. Three years ago pain appeared in the upper division of the fifth nerve. It started on the slightest provocation. Mastication became so painful that nothing but liquid food could be taken. Laughing, sneezing, swallowing, crying, all occasioned exquisite pain. For a year previous to the operation pain was almost continuous, and there were occasional exacerbations of such severity as to produce delirium. Nourishment could only be taken in small quantities, and, as a consequence, she became emaciated and weak. Dr. Henry Schweig, under whose care she was at this time, informed Dr. Howe that he administered morphine hypodermically, endermically, and by the mouth, with and without atropine, without any alleviation of the pain. He could not administer more than fifteen minims of Magendie's solution without aggravating the mental trouble, so that it was impossible to give heroic doses of the drug. He also tried aconitine without any effect. At Dr. Howe's request, he also tried hypodermics of strychnine and of atropine, but without avail. The galvanic current was also tried for four weeks, with no effect. The only drug from which an appreciable effect could be obtained was nitro-glycerin. This medicine relieved the pain for two or three weeks, and then failed like the other remedies. The doctor then brought her to St. Francis's Hospital, and Dr. Howe performed Carnochan's operation on May 29, 1883, removing the superior maxillary branch of the fifth nerve and Meckel's ganglion. For three days after the operation the patient slept well, and there was little or no pain excepting that which naturally resulted from the operation. At the end of that time she had severe pain in the region of the inferior dental nerve and spasm of the muscles of the affected side. This disappeared and was replaced by a dull pain in the wound and in the ear. A drainage-tube was inserted, and through this a solution of chloral, ten grains to the ounce, was injected twice each day. This re-

lieved the pain. She left the hospital on June 11th, almost entirely free from pain, and able to eat and sleep and to live comfortably. It was now seven months since the operation. She had gained in weight and strength, and was free from pain unless exposed to very sudden changes of temperature. She ate and drank with comfort, and considered herself greatly improved by the operation. Notwithstanding this good result, Dr. Howe was not in favor of the operation, as he thought further experiments with medicines would give the same result, more especially by resorting to the hypodermic injection of strychnine.

DOUBLE GENT VALGEM; OSTEOTOMY BY MACEWEN'S METHOD.

—Dr. W. T. BULL presented a patient with the following history: J. H. H., aged sixteen, an errand boy, was admitted August 15, 1883, with the statement that for the preceding two years both his knees had been growing weaker, knocking against each other while he was walking or standing. This condition had grown much worse during the past four months. His family history was good, and his general health had always been good. When he stood with his knees in apposition, and with his feet as closely approximated as possible, the distance between the internal malleoli was 8.4 inches. When he lay on his back this distance was 9.25 inches. The knee joints were perfectly normal. The internal condyle was elongated. August 24th, at 2:30 P.M., the patient was etherized, Dr. Bull and Dr. Little operating. An incision was made on the inner side of the right thigh, through the skin and underlying tissues down to the bone, according to Macewen's method. The bone was then partially divided by chiseling, the remainder of the bone being fractured by manual force. The small hemorrhage was controlled by pressure. The limb being forcibly straightened, the following dressing was applied: A small peat-bag was placed over the wound, and a full Lister dressing applied from the ankle to the gluteal fold; over this was placed a loose plaster-of-Paris splint. During the operation a stream of solution of salicylic acid was constantly projected over the wound; before applying the dressing the wound was cleansed with a solution of bichloride of mercury, 1 to 1,000. The same operation was then performed on the left leg, and a similar dressing applied. At 7 P.M. the patient had made a good recovery from the ether. He complained of considerable pain in the left foot. This pain increased, and became so severe by 12 P.M. that the splint was cut open and the limb held in position by properly adjusted sand-bags. Five minims of Magendie's solution of morphine were administered hypodermically.

August 25th.—The pain continued. In both feet there was a sensation of numbness, with well-marked signs of retarded circulation. The morning temperature was 99.2° F., the pulse 96. At 12 M. both dressings were removed, and fresh Lister dressings were immediately applied. Long side-splints, reaching from the axilla to the ankle, were applied. The circulation began to improve, and in a few hours was apparently normal. The temperature was 100.8°, the pulse 105. The general condition of the patient was very good.

August 26th.—During the following seven days the patient had a slight evening rise of temperature, with a pulse varying from 90 to 104. The temperature was normal on the ninth day, and continued so during the remainder of the treatment.

September 11th.—The dressings were removed. The original incision was nearly healed. Simple dressing was applied with long side-splints.

September 14th.—A plaster-of-Paris splint was applied from the toes to the groin of each leg.

October 23d.—The splints were removed. The right leg was found to be in excellent position. There was some slight

tendency to a bending inward of the left knee. Rubber bandages were then placed around each knee joint, and the patient was allowed to walk about.

December 15th.—The bowing inward of the left knee was almost entirely rectified by a brace which extended from the sole of the foot to the upper portion of the thigh, with a hinge joint at the knee.

SUBTROCHANTERIC OSTEOTOMY OF THE NECK OF THE FEMUR FOR CONTRACTURE AND ANKYLOSIS OF THE HIP.—Dr. BULL also presented a patient illustrating the result of this operation: Mary C, ten years of age, a native of the United States, was admitted to St. Luke's Hospital, September 14, 1883. She had been healthy until three years and a half old. Then, without an injury, hip-joint disease began to develop on the left side. She was treated for five years at the Hospital for the Ruptured and Crippled. The patient left that hospital when eight and a half years old, with the limb in good position. Very soon afterward, contracture of the hip joint set in, and had increased rapidly during the past six months. On admission, the left thigh was flexed and adducted, so that the patella was situated two inches and a quarter above the opposite patella and outside of the median line of the right thigh. When the patient lay on the back on a table the thigh was ankylosed so as to form nearly a right angle with the longitudinal axis of the body. Except for a very slight flexion of the femur, mobility at the hip was wanting, except when she was under the influence of ether. Under ether a small amount of motion was possible. When she stood erect, the toes of the left foot were about five inches from the ground, and the heel was fully a foot above it. In walking, the patient placed the toes of the left limb only to the floor, and locomotion was performed in a hopping style. The pelvis was very decidedly tilted downward on the left side, and the lateral curvature of the spine was extreme. Motion in the knee joint was perfectly normal. The head of the trochanter on the left side was one inch and a half above Nélaton's line. There was muscular atrophy of the left thigh, which showed a diminution of two inches in circumference.

October 4th.—Tenotomy was performed on the gracilis and adductor tendons, with open division of the fascia and tendons below the superior spinous process of the ilium. The femur was divided just below the trochanter major, and a wedge-shaped piece was removed, the base of which measured half an inch. The Lister dressing and a long side-splint were applied, together with extension.

October 26th.—The wound of the femur was entirely healed, and the other wounds were nearly closed.

November 9th. union of the femur was solid, the left leg being shortened two inches and a quarter.

TRAUMATIC ANEURYSM OF THE VERTEBRAL ARTERY.—The PRESIDENT presented a patient who had had this affection, and remarked that there were ten cases upon record. Of thirty-two cases of wound of the artery collected by Fischer, nine terminated in aneurysm. For the injuries to this vessel the carotid had been tied twelve times with an unfavorable result. In the aneurysmal cases the carotid artery had been tied five times, the patients all dying. Once it was exposed, but not tied, and that patient recovered, but why was not clearly to be seen. In two cases the aneurysm was cured by cutting down, opening the sac, and plugging the opening in the artery. In the patient presented this evening, the aneurysm was cured by digital compression. The man was twenty-eight years of age, and on the 8th of December was struck with a knife half an inch below the lobe of the right ear just behind the jaw, his opponent standing in front of him and holding the weapon in his left hand. Considerable hemorrhage took place, though when the man entered the hospital he was not very much exsanguinated, and,

the bleeding having ceased, an iodoform pad was simply placed over the wound, which was not disturbed until the tenth day, when the dressing was removed and the wound found healed. Forty-eight hours after the receipt of the wound the patient experienced a peculiar sensation in the head, and sudden paralysis developed, involving the opposite arm, from which he had not yet entirely recovered, although there had been marked improvement in this respect recently. After the removal of the dressings a slight swelling at the posterior margin of the sternocleidomastoid muscle and just below the mastoid process was observed. This tumor had a feeble pulsation, which gradually increased up to the beginning of last week, when the signs of an aneurysm were strongly marked over a space two inches in diameter, and a *bruit* was heard. The diagnosis was made positive by pressure on the carotid artery; when this was made upon a level with the thyroid cartilage, pulsations with swelling were not arrested, but when pressure was made on a level with the tubercle of the sixth cervical vertebra, pulsation with tumor was at once arrested, and when the pressure was removed it immediately returned in full force again. The diagnosis was in this way made clear, and was corroborated by his colleague, Dr. Markos. The question was, What should be done? The best suggestions which he had seen upon this subject were those by Holmes in his article on aneurysm, written in 1873. Dr. Weir finally determined, before opening the sac and plugging it, which had afforded the best outcome of treatment, first to apply ice, and, if that failed, to resort to digital compression, because he had found that pressure upward and forward upon the lower portion of the tumor arrested the pulsation. He therefore secured a relay of medical students, and last Thursday, after having used ice for some days without any change in the tumor, he began the treatment by digital compression at twelve o'clock. At two o'clock the pulsations were almost arrested, and at three o'clock they had entirely ceased, but the pressure was kept up lightly until seven o'clock. Since that time there had been no trouble in this region, and the tumor had rapidly subsided. No cerebral trouble ensued during the treatment.

Dr. L. A. STIMSON said he could add one case to the list of unsuccessful ligations of the common carotid artery for wounds of the vertebral artery. The patient was in Bellevue Hospital. He had been wounded by a pistol-ball, which entered the mouth, passed into the left side of the pharynx, and made its exit at the back of the neck. There had been a profuse hemorrhage, but when he saw the case the bleeding had ceased. The hemorrhage recurred the next day, and the common carotid was tied by the house surgeon. The patient died within a few hours afterward. At the autopsy it was found that the ball had passed between the atlas and the skull, and had divided the vertebral artery.

Dr. W. S. HALSTED referred to a case which he had seen at the Chambers Street Hospital. It was one in which the patient had received a stab with a pen-knife between the atlas and the occiput, producing paralysis on the opposite side, and of the muscles supplied by the spinal accessory nerve upon the same side, and the vertebral artery was not injured.

REMOVAL OF LARGE URETHRAL CALCULI BY INCISION THROUGH THE PERINEUM; WEIGHT OF CALCULI 414 GRAINS.—Dr. J. W. HOWE presented a specimen with the following history: An Italian, aged thirty-one, was admitted to the surgical division of St. Francis's Hospital on December 31, 1883. At the age of thirteen he had been troubled with stone in the bladder, which was removed by an Italian surgeon through an incision in the perineum. The wound in the perineum only partially healed, and a fistula remained, through which the urine escaped for several months. Some time afterward the patient passed a small calculus through this opening. The exact time of this occur-

rence the patient did not remember. Shortly after the expulsion of the stone the opening in the perineum closed, and he had no further trouble up to within five years of the date of entrance to the hospital. He then noticed a hard mass in the perineum, which gave him some pain on pressure, as well as pain on micturition. The mass grew slowly, with an increase in the pain. It was easily moved from side to side. A friend advised him to poultice the swelling in the perineum. After following this advice for a few weeks the integument ulcerated, and a calculus of the size of a pigeon's egg was extruded. The patient likened this mass to a piece of hard rubber. From the passage of this stone the patient experienced great relief, and he had no special trouble for four years, when he noticed two protuberances in the perineum, which gave him pain on pressure, as well as pain on micturition. The pain during the passage of the urine was of a burning character, and lasted some time after the urine was voided. There was also considerable difficulty in emptying the bladder. These prominences continued to increase until the patient's admission to St. Francis.

On examination, Dr. Howe found two prominent enlargements occupying the median line of the perineum. They were both easily moved, or rather the tube in which they were contained readily moved from side to side. The upper tumor was about half an inch from the lower and larger one below. They could, however, be drawn together, and by the rough grating their character could be made out. The upper end of the first calculus was situated about three inches and a half from the meatus. The second and larger one extended down to within half an inch of the anus. The patient did not seem to suffer much pain when they were handled.

On Saturday last, the 5th of January, the patient was etherized. The meatus, which was very narrow, was incised so as to admit a No. 18 American sound. Its passage down the urethra was unobstructed until the first calculus was reached. A No. 5 was then introduced, but failed to pass the obstruction. An incision was made in the median line of the perineum, extending from the middle of the upper calculus, at the upper boundary of the perineum, down to within three quarters of an inch of the anus. The upper stone was then pushed into the opening and extracted; the lower one was then removed by completing the incision through the perineal tissues. A further examination showed that the urethra was very much dilated from the lower calculus to the bladder. Dr. Howe first passed one finger in through the neck, and discovered another calculus inside the bladder. He then introduced a second finger along with the first one, stretching the parts easily. A stone forceps was then introduced, and the cystic calculus was removed. The calculus which occupied the anterior portion of the urethra was found to weigh 135 grains (troy). It measured one inch and a half in length, and three quarters of an inch in its broadest diameter. The lower calculus weighed 279 grains, and was one inch and three quarters in length, and one inch and a half in its broadest diameter. The calculus taken from the bladder weighed 395 grains; it was two inches in length, and one inch and one eighth in its transverse diameter. The patient's temperature the night before the meeting was 99.5° F., and he was doing well so far.

Dr. A. C. Post said there was a case on record in which a stone passed spontaneously from the female urethra, and was said to have been as large as a goose's egg. He thought a number of cases of this kind had occurred in both sexes in which stones of very considerable size had passed through the dilated urethra. He was not able to give the particulars of a number of cases occurring in the practice of his son in Beyroot, but his impression was that in some of them the calculi were larger than that presented by Dr. Howe.

NEW YORK NEUROLOGICAL SOCIETY.

A STATED meeting was held January 8, 1884, Dr. WILLIAM J. MORTON, President, in the chair.

NOTE ON THE USE OF THE MENTHOL CONE AS AN ANODYNE.—Dr. E. C. WENDT showed a little contrivance, called by the Germans "*Migräne Stift*," and explained the method of its application and uses. It consisted of a piece of menthol molded into a conical shape and secured in a little wooden box, closed by a cover to prevent evaporation, soiling, and breaking. It seemed to be very little known here, although it was much used abroad, especially for sick-headache. His attention had first been directed to the anodyne properties of menthol by a short notice published in the "*Medical Record*" of April 28, 1883, by Dr. Cammann. That gentleman had recommended an alcoholic solution of menthol (3 j to 3 ss. of alcohol) to be painted over the affected parts. Dr. Wendt had since that time often used this solution, and found it a rather reliable anodyne. Its pain-relieving action was restricted, however, to the slighter ailments, especially those of a neuralgic character. Since his acquaintance with the solid menthol cone he had frequently substituted the direct application of menthol, by means of the latter, for the solution formerly employed. He would admit that the only advantage which the solid cone or pencil had over the solution consisted in the greater simplicity of its application, its ready portability, and the fact that its vapor was not apt to irritate the eyes of susceptible patients. He had repeatedly heard complaints in that direction from ladies regarding the solution, which was obviated by using the cone.

In this country menthol had not yet received that amount of recognition from the profession to which its pain-obtunding properties would seem to entitle it. In fact, little seemed to be known about it, and for this reason Dr. Wendt thought it might not be amiss to quote a descriptive notice which had appeared in the "*Midland Medical Miscellany*" of October, 1883: "*Menthol, or menthylie alcohol, C₁₀H₁₈O, is a crystalline substance, deposited from the oil of peppermint, prepared in China and Japan from *Mentha arvensis*, var. *pipereacens* and *glabrata*."*

It formed the chief ingredient of a much-valued remedy for neuralgia before its nature or source was generally known. Under the name of "*Po-ho-yo*," or *gouttes japonaises*, it had been sold in small bottles, labeled with Chinese characters. It was a white crystalline stearoptene, melting, when pure, at 97° Fahr., and was obtained by the Japanese from the oil of peppermint by submitting it to freezing several times in succession until no more menthol crystallized out. It was also said to be contained in the American and English oils of peppermint, but probably in small quantities only. It was somewhat surprising that the Japanese peppermint-plant, which was grown in England as a curiosity, had not been cultivated in that country as a source of the drug, the supply of menthol being uncertain, the demand great, and the price in consequence occasionally very high. Menthol was said to be sometimes adulterated with crystals of Epsom salts, to which it bore a great resemblance. These, being insoluble in alcohol or chloroform, in which fluid menthol was freely soluble, could easily be detected. Samples of fine crystals sometimes contained some essential oil adhering to them, a fact which must be taken into consideration when the menthol was made into cones or pencils. Menthol was but slightly soluble in water, although imparting a strong odor and taste to that liquid, and was soluble in aqueous alkalies. It was soluble in fixed and volatile oils and in ether.

Although Dr. Wendt's experience with menthol had not yet been a very extended one, it had nevertheless been sufficient to convince him of the utility of the drug in a rather large class of

cases. Thus, as already stated, he had found it a pleasant and reliable anodyne in all the lesser neuralgias, and especially in those so frequently occurring about the face. But it was also serviceable in many painful affections due to inflammatory processes—for example, in mumps, in the cervical adenitis so often accompanying sore throat, and in numerous other affections where pain was a prominent symptom, menthol might be used to advantage. With regard to its topical action, it was similar to that of aconite, over which it had the advantage of not being poisonous. Dr. Wendt remembered one rather striking case of quite severe supra-orbital neuralgia which did not yield to the oleate of aconite, but was much benefited by the menthol. But, on the whole, in violent attacks he had found it almost useless. In typical migraine, for instance, where the pain was at all severe, and in all deep-seated aches, of more than very moderate intensity, it had no appreciable effect, except, perhaps, the indirect psychological action of distracting the sufferer's attention.

Dr. ROBERTS asked Dr. Wendt if he had tried the prolonged application of menthol.

Dr. WENDT said that he had in some cases of hemicrania, though without decided benefit. Nevertheless, the patients experienced a pleasant sensation of coolness of the surface, followed by a feeling of agreeable warmth.

The PRESIDENT asked Dr. Wendt in what sense he used the word anodyne.

Dr. WENDT said, in the usual one of affording relief from pain by blunting sensibility.

The PRESIDENT thought that menthol probably acted more after the manner of counter-irritants, by insuring relief in a reflex rather than directly local way. Mustard was a typical peripheral nerve-irritant, and it seemed to him that the action of menthol could be best explained on the same principle of procuring peripheral nerve-impressions in a reflex way. His attention had first been called to the menthol cone by Dr. Wendt. He chanced to be at the latter's office one day when suffering from a headache. A few strokes of the menthol gave him at once a sense of relief. He felt the effects of the peppermint to be as gratefully cooling as the application, say, of cold metal. In brachial neuralgia, as well as in sciatica, he had been pleased with the good effects of menthol. He thought the drug was deserving of further trials.

DETENTION IN ASYLUMS.—Dr. RALPH L. PARSONS read a paper in which he spoke first of the question whether sane persons were not often improperly or unjustly detained in asylums for the insane; and, secondly, whether many incurable and incurable patients who were now methodically detained in asylums might not advantageously be returned to their relatives, or placed in the care of private families under State supervision.

It was assumed, in the first instance, that the detention of patients, after recovery had taken place, for a longer time than might be required was quite possible, and even probable, in some instances. But he thought that such detentions were not usually of serious import to the patient; that, on the other hand, too early discharge might be more injurious. It was also admitted that maliciously unjustifiable detentions were quite possible, as any other sort of injustice was possible on the part of persons holding positions of power and responsibility. But reasons were urged by Dr. Parsons in support of the belief that such malicious detentions were at least very rare; that sentiments of honor and professional pride were strong deterrents, to say nothing of the great danger of detection in the commission of the wrong, and the ease with which patients who were decidedly insane obtained their enlargement through the intervention of the courts.

Cogent reasons were given why various classes of convalescents ought to remain under asylum care for a period of time after they appeared to be well; as, for instance, when they would be immediately subjected to the exciting cause of their insanity on their return, when the progress toward convalescence had been characterized by relapses, or when dangerous delusions had been entertained and had faded away so gradually that there were difficulties in judging whether they had passed away entirely. But, on the other hand, the discharge of certain uncured curables before they were well was advised, as when, after making a certain degree of improvement, this improvement stopped and the patient seemed to retrograde. It might be safe and highly advisable to discharge some of these patients before they were well.

The major part of the paper was devoted, however, to an advocacy of the discharge of harmless incurables and their return to the care of their friends, or of placing them with ordinary families as borders and in some sort as members of the families. It was maintained by the reader that, however comfortable and happy such patients might appear to be in large asylums, there were many causes of annoyance and discomfort that would not be experienced in ordinary family life; that, notwithstanding the fine buildings they occupied, and their freedom from care, they were still prisoners and exposed to many disagreeable associations and associates. Quotations were made from Dr. Bucknill and from Dr. Maudsley strongly supporting these views.

The question was then considered, what classes of incurables might safely, and with benefit, be released from asylum restraints. It could be said of those only who were quiet and orderly, and required no special attendance or supervision. Habits of industry would be favorable. Whether such patients would do better with their relatives or with strangers would depend on the circumstances of the family, the state of health, the surroundings, the feelings or notions of the patients, etc. It would be found, however, that many patients who would not do well with their own kindred would be happy, contented, and useful with congenial strangers. It would be impossible for the patient to resume his former position and influence in his own family, and hence he would be subjected to irritating restrictions and annoyance there.

As a preliminary measure, a system of legalized furloughs was advocated, to the end that at first the patient might still be under legal restrictions and easily returned to the asylum, if the trial at large should prove a failure. Properly constituted authorities should make the selection of patients for the trial, with the assistance and under the advice of the asylum superintendent. The families in which the patients were to be placed should be selected with great care. While at first there might be found very few suitable families that would assume the charge, it was thought that when a beginning had been made, plenty of suitable homes would be offered. Reference was made to the multitude of respectable and responsible families who took summer boarders for a moderate compensation, and to the probability that some of these families would prefer one or two permanent patient boarders to a number of summer boarders for a short season during the busiest portion of the year. A suitable system of visitation and of reports was advocated. The paper closed with the following summary of conclusions:

"1. That, inasmuch as many recoveries take place in asylums for the insane, it is to be expected that some convalescent patients may at any time be found in the wards.

"2. That, while possibly now and then a convalescent patient may be detained on probation an unnecessary period of time, such cases are not of frequent occurrence, nor important

in their consequences when they happen; and that, when they do occur, the detention is very rarely indeed through criminal intent.

"3. That many harmless incurables are unnecessarily detained in asylums for the insane; that these incurables would be happier in the enjoyment of ordinary family life and associations, and that systematic efforts should be made to secure their enlargement and their establishment under family care.

"4. That, under certain circumstances, curable patients should be removed from asylum restraint and associations while yet uncurd."

The discussion upon Dr. Parsons's paper was postponed until the next meeting of the society.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Meeting of December 21, 1883.

The President, Dr. Tyson, in the chair.

FRACURE OF THE BASE OF THE SKULL.—Dr. GUY HINSDALE related the following case: J. H. W., aged fifty, fell on the ice December 8, 1883, striking upon the stone pavement. The blow was received on the left posterior part of the skull. The skin was not broken. Shortly afterward he was admitted into the Episcopal Hospital, totally unconscious; blood was found flowing from his mouth and left ear, and his nose contained clots. His pupils afforded no evidence of his condition, because of iridectomy having been performed on both eyes some years before. He talked incoherently, and his breathing was labored and at times stertorous. Paralysis of the left leg was noted. Blood continued to issue from the left ear, and on the second day the discharge became thin. It continued serous until death, which occurred on the eleventh day. The urine was examined several times, and found to contain sugar in moderate amount, but no albumin; it was passed freely. He never regained consciousness, but became more stupid, and the paralysis of the leg remained. At the autopsy a superficial clot was found over the brain beneath the seat of injury; over the right frontal region there was a very large one beneath the membranes, filling the sulci between the convolutions. This was the result of the counterstroke, the force having been first received at a point diametrically opposite, and fully accounted for the left-sided paralysis. The fracture was slightly over five inches in length, extending from a point in the left occipito-parietal suture, an inch and a half behind the temporal bone, across the suture, through the petrous portion and the auditory canal, close to the inner side of the foramen ovale, toward the foramen rotundum, where it terminated.

NECROSIS OF THE TEMPORAL BONE; ABSCESS OF THE BRAIN.

—Dr. HINSDALE also showed a specimen removed from the body of Margaret P., aged forty-six, who died in the Episcopal Hospital September 21, 1883, after long-standing aural disease. In early childhood she had scarlet fever. This was followed by aural catarrh, and the discharge from the ear continued until her death. She stated that, when twenty-two years of age, a polypus could be seen in her ear, and that it was removed fifteen years ago. Other masses had been removed on three occasions within the past three years. In May, four months before her death, she consulted Dr. Burnett, and at that time her appearance was most wretched—she was extremely weak, pallid, and emaciated. Paralysis of the right side of the face had occurred during the previous winter without the supervention of additional ear symptoms. At the time of examination there was great sensitiveness of the auriculo-temporal nerve, and she complained of intense pain over the right temporal bone. To control this pain, she was accustomed to use morphine supposi-

tories. Examination revealed a mass of granulations filling the entire lumen of the auditory canal, half an inch from the entrance. Late in May a large polypoid mass was extracted. Bare bone was then discovered on the posterior portion of the canal, and the channel was narrowed and blocked with granulations. About two fluidounces of blood escaped after the removal of this mass.

When Dr. Hinsdale saw her at the hospital, in September, she was in a very low state and evidently near her end. Her mind was seriously affected, conversation was impossible, and she groaned with the pain, which large doses of morphine would not altogether control. There was a moderate but constant discharge of pus from the ear, and from a sinus which had formed above the meatus. The whole temporal region was boggy; the probe passed in freely over an inch, and loose particles of dead bone could be felt in every direction. The disease had long been beyond the reach of any remedy, and there was nothing to be done but relieve pain and await her death.

The specimen removed embraced portions of the right temporal, parietal, and occipital bones. Almost the whole of the temporal bone had been destroyed, only the mastoid process and the upper border of the squamous portion remaining; an area of bone an inch and a half by two inches in extent had disappeared entirely. Adjacent to this region, and lying next the middle fossa of the skull, was a brain abscess, the walls of which were greatly thickened. On opening this cavity, about an ounce of thick, yellowish pus was found. A probe reached this cavity easily through the auditory canal and through the sinus above it, and many loose fragments of bone were encountered. The styloid process was found loose, but held in position by the ligaments arising from it. The inflammatory process, in which, of course, the meninges had shared, was not acute; the brain-substance beyond the abscess walls had no unusual appearance, and the left cerebral lobe, with its membranes, was normal.

Dr. C. H. BURNETT said that the great amount of bone tissue destroyed was remarkable. The necrosis seemed to have originated in the tympanic region rather than in the mastoid, and belonged to the class of cases second in frequency, the most frequent being those fatal cases where the bone disease originated in and extended from the mastoid cavity. Extensive granulations in the external auditory canal constituted a very unfavorable feature, as they dammed up the products of inflammation in the tympanic cavity and the mastoid cells, and forced them to break through more important and vital tissues. The case was another example of the evil of neglecting purulent disease of the ear. He would ask whether there had been symptoms of destruction or implication of any of the nerves passing through the cavernous sinus, such as would be shown by alteration in the parts supplied by the oculo-motor, the pathetic, or the ophthalmic nerve.

Dr. HINSDALE replied that no eye symptoms had ever been detected.

PHIBISIS WITH EMPYEMA.—Dr. H. M. FISHER related a case, from notes furnished by Dr. George M. Boyd, the resident physician of the Episcopal Hospital. A man, twenty-one years old, was admitted, March 17, 1883, with the history that he had had a slight cough for a year, but had not been annoyed with it until a month before, when he was seized with severe pain in the left side of the chest, accompanied by chilly sensations and difficulty of breathing. On admission, he presented all the symptoms of left pleural effusion—absence of vocal fremitus, with tubular breathing and bronchophony in the neighborhood of the spinal column on the left side. His chest was tapped on the morning of March 21st, and three points of a semi-purulent fluid were removed. This was followed by great improvement in the symptoms. Three weeks later he left the hospital, con-

trary to advice. He was admitted again April 20th, and stated that, soon after leaving the hospital, the pain in the left side returned, and was followed by dyspnoea. On the 23d paracentesis thoracis was performed by Dr. Henry, fifty-six ounces of fluid being drawn off, and the operation again afforded great relief. A violent fit of coughing followed the withdrawal of the cannula. Before the operation, the heart's apex-beat was found to be immediately below the right nipple; after it, it was found to have shifted to a point an inch to the left of its previous position. May 5th, Dr. Forbes operated, at Dr. Henry's request, making two openings into the left pleural cavity—one at the fifth interspace, the other at the fourth and to the right of the first. Ten ounces of purulent fluid were withdrawn by means of the aspirator, and a soft-rubber catheter was passed in at one of the openings and out at the other. The pleural sac was then ordered to be washed out daily with a solution of corrosive sublimate (one grain to the ounce).

During the summer the patient's general condition seemed to improve for a time; his appetite, however, continued obstinately bad, and he had constipation alternating with diarrhoea. In October it was noted that he was losing flesh and strength rapidly, and that there was much oedema of the feet and legs. During that month diarrhoea became a constant symptom, and death occurred November 22d.

Post-mortem Examination, ten hours after death.—The body was extremely emaciated. The left lung was contracted to about one fourth of its normal size, and contained some cheesy masses in its upper lobe, with areas of catarrhal pneumonic infiltration. The left pleural cavity contained about five ounces of ichorous pus. The parietal layer of the left pleura was so tightly adherent to the chest-wall that it was impossible to detach it without dissection. The pulmonary layer was also tightly adherent to the lung, the lobes of which were firmly matted together by adhesions. The right lung also presented numerous cheesy foci, with large areas of catarrhal pneumonic infiltration. The heart was rather small, and its tissue was pale, but its valves appeared normal. The liver weighed six pounds and six and a half ounces, its tissue was pale, and it had a decidedly waxy appearance. The spleen was much enlarged, and its tissue was firm and of a dusky-red hue. Numerous yellowish-white nodules were seen in it, the largest of which was perhaps of the size of a small pin-head. The kidneys were rather large, their capsules were non-adherent, and their tissue was rather paler than normal. Numerous minute, whitish nodules were also found scattered through the tissue of both kidneys; they appeared somewhat more numerous and larger in the cortical portion, but were also found in the medullary portion. From some of the larger nodules a whitish, puriform substance could be squeezed out with the blade of the knife. With the naked eye the exact nature of the above-mentioned infiltrations of the spleen and kidneys was difficult to determine. Nothing abnormal was noticed in the intestinal tract, except in the ileum, where on an area of intense congestion was noticed about one yard from the ileo-cæcal valve, but no ulceration was anywhere detected.

Dr. Fisher thought the sequence of pathological events had been as follows: 1. Catarrhal pneumonia, with the production of cheesy foci. 2. Scrofulous inflammation of the pleura, with attendant exudation, which from the start was probably more or less purulent. 3. Infiltration of the liver, the spleen, and possibly the kidneys also with amyloid matter. The exact nature of the yellowish-white nodules in the spleen and kidneys being still undetermined, he could not assign to them a positive place in the chain of scrofulous processes, but, from the absence of any macroscopic evidence of embolic infarction, or of any appearance of infarction in the one microscopic section of the

kidney that he had had an opportunity to examine (kindly made for him by Dr. Henry), he would conclude that these also were cheesy foci, and perhaps their production might have nearly coincided in point of time with that of the cheesy foci in the lungs before alluded to.

Dr. SHAKESPEARE said that the specimen was a good example of milary tuberculosis. The small collection in the spleen might be tuberculous, and should have been examined for tubercle bacilli. He alluded to the successful employment of very weak solutions of corrosive sublimate in washing out suppurating serous cavities.

ATHESOMA, DILATATION, AND ANEURISM OF THE AORTA; RUPTURE INTO THE LEFT PLEURAL CAVITY; CONGENITAL DEFORMITY OF THE STOMACH; MALPOSITION OF THE TRANSVERSE COLON AND RIGHT KIDNEY; IRREGULAR SHAPE OF THE KIDNEY; ANOMALOUS ORIGIN OF THE RENAL ARTERIES AND OF THE URETERS.—Dr. J. H. MÜSSER presented a series of specimens from the body of a patient who had been under the care of Dr. Ludlow, in the Presbyterian Hospital, for nasal catarrh. He complained of a slight bronchitis also, but only the nasal trouble was treated. He was a man sixty-three years old, well-nourished, of temperate habits, by occupation a wheelwright, who had had no previous illness. He was under observation ten weeks. The night before his death he slept well until 5 A. M., when he told the night nurse that he was very cold. After being covered, he apparently went to sleep; an hour afterward he was found dead. At the post mortem, twelve hours after death, the abdomen was found moderately distended, with a decided swelling in the right lower quarter, almost filling that area, resonant on percussion. This was found to be due to the cæcum and the transverse colon. The ascending colon extended about half the usual distance in its ordinary course, and then turned at an acute angle into the transverse colon. The latter descended parallel with the former into the right iliac fossa, and thence ran diagonally upward across the abdomen to the usual place of junction with the descending colon. The right lobe of the liver could not be seen until the ribs were removed, when it was found two inches above their margin, and measured only two inches and a half in the nipple line. In the median line this same vertical length was three inches and a half. More of the left lobe was visible than of the right. Along the edge of the left lobe the stomach extended four inches and a half from the median line. It appeared to be small. When removed, it was found to be divided by a constriction five inches from the fundus; from this constriction to the pylorus the measurement was four inches and a half. The cardiac end was much smaller than normal; the walls and the mucous membrane were healthy. The second portion was a mere tube with thick walls. The thickening was due to hypertrophy of the longitudinal muscular layer and to the folds that the mucous membrane was thrown into. These folds were very marked, longitudinal, and congested on their crests. The peritonæum was opaque and thickened. The capsule of the liver was thickened and opaque along the edges of the right lobe. There were cicatrices on the convex surface of the organ, and at one point it was firmly adherent to the diaphragm. Its tissue was firm on pressure and congested. Incipient cirrhosis was noticed at the microscopical examination. The left kidney was found in its normal position. It was much enlarged, being five inches long and two inches thick. Its pelvis was filled with fat. Its substance was pale, and hard on pressure; its cortical portion was contracted, and its capsule was readily torn off. The right kidney was found in the pelvis, at the right sacro-iliac articulation. It was small, irregular in shape, and parallel with the sacrum in direction. The portion dipping downward tapered to a point, being half an inch in width; the upper portion

was two inches wide. Toward the small end of the kidney the hilum divided, one part extending upward for an inch along one side of the organ, the other the same distance on the other side. The renal artery arose from the normal point of origin of the middle sacral. It divided into two branches; one of these, two inches and a half long, entered one lateral hilum (if it could so be called); the other divided at a point two inches and a half from the main trunk, one subdivision entering the remaining lateral hilum, and the other running across the floor of the pelvis to the normal end of the kidney. The ureter arose by three branches—two from the upper end and one from the smaller end.

The left pleural cavity was almost filled with blood, on which the lung was floating. The lateral surface was adherent to the aneurysm. In its removal the collapsed sac was seen on the left side of the vertebral column. The heart was enlarged, especially its left side, weighing eleven ounces and a half. The mitral valves were a little thickened; the aortic were healthy. There was atheroma of the aorta, from its beginning to the celiac axis. A calcareous plate was found in the celiac axis. From its origin to the middle of its transverse portion the aorta was dilated. Opposite the trachea its caliber was diminished almost to the normal size, and at that point there were marked sclerotic changes. At the junction of the transverse and descending portions the lumen was closed again, and it was here that the aneurysm originated. It was of the true variety, and measured five inches and a half in length, and, when distended, twelve inches in circumference. Four false aneurysms sprang from it. The sac had burst behind the pleural adhesions. The vertebrae were not eroded, and, although the sac was in contact with the left bronchus, there was no evidence of decided pressure upon the latter, while the relations of nerves, other vessels, and the esophagus were such that the usual pressure symptoms could not arise. Thus it would be seen that only physical examination could have detected the aneurysm during life, and there was nothing in the subjective symptoms to call attention to the state of the thoracic contents.

CONGENITAL HOUR-GLASS CONTRACTION OF THE STOMACH.—Dr. Musser also showed a stomach that had been removed from the body of a patient who had died of organic heart disease. There was constant vomiting a few months before death, but it was due to the patient's general condition, and not to the gastric changes. Dr. Musser called the condition congenital, because there had been no clinical history to indicate any disease that would account for it. The contraction took place in the center, and was transverse; the peritoneum and the submucous connective tissue were thickened at that point. In front of the constriction the muscular coat was hypertrophied. The mucous membrane was thrown into folds by the constriction.

PLEURO PNEUMONIA COMPLICATED WITH DELIRIUM TREMENS.

Dr. Musser presented this specimen also. It was the lower lobe of the right lung in a state of red hepatization. Almost the whole pleural surface, including the diaphragmatic portion, was covered with recent lymph averaging half an inch in thickness. The tongue of the lung dipping into the space between the diaphragm and the thoracic wall was not solidified entirely. Here the lymph was abundant, and the contiguous portion of the lung was hepatized, as if the inflammatory process had extended near the pleura. The patient had died eighteen hours after his admission into the hospital, of heart-clot. There had been evidence of its formation when he was admitted, and, in addition, he had delirium tremens. The pneumonia was distinctly recognized, but there were no signs of simple or diaphragmatic pleurisy. Extreme distension of the right side of the heart was noticed at the autopsy, on raising the sternum, and especially of the auricle. On opening the heart, hypertrophied from other

causes, the right side was found filled with blood, and an enormous ante-mortem clot twined around the leaflets of the tricuspid valve, and extended through the auricle into the pulmonary vessels. A similar clot was found in the left side of the heart. The kidneys were congested and there was incipient cirrhosis. The man had been on a spree for two weeks, and, five days before admission, he had a severe chill, followed by the symptoms of pneumonia. Two days after the chill the mania developed, and on the day of admission he had been found wandering about the streets. He was forty-one years old.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of December 19, 1885.

WHAT IS MEANT BY NERVOUS PROSTRATION?—Dr. ROBERTS BARTHOW read the following paper:

The popular conception of the condition now known as "nervous prostration" is a state of debility, in which nervous derangements predominate. A man actively engaged in business or in public life presently finds himself unequal to his daily tasks; he suffers odd sensations in his head; his digestion is disordered; he is weak; wakefulness, mental depression, and a thousand and one new sensations of strange character and fearful portent are superadded. The unfortunate subject of these ills now recoils from his work, gives himself up to the consideration of his symptoms, and relaxes his hold on the interests and occupations of his life. All the world declares that he has "nervous prostration," and this explanation satisfies. Physicians say "neurasthenia" or "hypochondria," according to their habits of mind or to their training. Sometimes this condition is called the "American disease." Indeed, there is a general notion, widely prevalent, that neurasthenia is a peculiarly American malady. The late Dr. Beard was the apostle of this dispensation, and he not only was noisy and persistent in his advocacy of that view, but claimed, indeed, to have first clearly defined neurasthenia, and to have classified under this designation the numerous symptoms pertaining thereto. If we can not admit Dr. Beard's claim in its entirety, if we experience repulsion at his tremendous but unconscious egotism, we are still compelled to acknowledge that his work in this connection is the most important that has appeared. He was peculiarly fitted to differentiate this malady by reason of the quickness and acuteness of his intellect, his power of analysis in its subtlest aspects, and his far-reaching, his omnivorous faculty for related facts.

The term *neurasthenia*, advocated by Beard, is by no means of recent origin. The corresponding French word, used in the same sense as we now employ it, has been a stock word of French neurological medicine for fifty years. Under the terms spinal irritation, hysteria, hypochondriasis, the nervous state, etc., symptoms of the same character as those now included in the word *neurasthenia* have been described. Besides the general state, similar derangements of functions of particular organs have been separately considered, as palpitation of the heart, headache, flatulence, impotence, etc. In the word *neurasthenia*—popularly, nervous prostration—the whole morbid complexus is included. The question I have to consider is whether this is a real, a substantive disorder. Are the notions now generally entertained about it founded on a true conception of the condition?

I need not enlarge on the importance of a correct understanding of a morbid state which is supposed to be due to the conditions of modern, especially of American, life. Without stopping now to question the soundness of the prevailing doctrine, I will place before you the clinical history of two cases, representatives of the two types of neurasthenia. These may be designated respectively as the *congestive* and the *anæmic* varieties.

The latter are greatly more numerous, but the former are not uncommon, as Beard admits.

CASE I.—THE CONGESTIVE TYPE.—Mr. —, aged forty-four, president of one of the largest railroad corporations of the West. He is now a robust man, 5 feet 10 inches in height, 196 pounds in weight, and has a very dark complexion, his type of constitution being the so-called bilio-nervo-sanguineous. Beginning his career at an early age in a subordinate position, he has, by the force of a superior intellect and of a physique that no labor could subdue, risen to the highest office, and now controls vast interests. Ambitious, enterprising, resolute, he has carried these faculties into all his work, and has shrunk from no tasks, however severe—from no responsibility, however onerous. As he has risen in position, social engagements have also added to his burdens. His mode of life has changed to some extent. His habits have become more sedentary, although diversified by frequent railroad journeys; the pleasures of the table, including wine-drinking and late suppers, have been more and more indulged in; excessive smoking has been added to these indulgences; and thus, while his physical powers have been slowly impaired by bad hygiene, the demands on his mental powers have increased. Extensive interests, uncertain, often precarious, business arrangements, and the incessant watchfulness required when vast combinations may be wrecked through failure at any point, demand the highest use of every faculty; and thus to work is added worry.

Three years ago Mr. — observed that he was not feeling well, and that he could not work as before. He became dull, especially after meals, had a constant headache, dizziness and throbbing of the temples; he applied his mind with difficulty, and all of the head symptoms were increased by the efforts made; he had a good, rather a keen appetite; a heavily coated tongue, flatulence, constipation, and some colic pains. The bladder was rather irritable, especially at night; sexual inclination had declined with lessened power, and various ill-defined but annoying sensations were felt about the penis, scrotum, and perineum. During the first year the symptoms increased; the attacks of vertigo were sometimes very severe, so that he had to support himself for a moment to save him from falling. On several occasions he became very much dazed, even lost consciousness momentarily, and once wandered some distance from the proper route he was taking. Anomalous sensations of creeping and crawling, coldness and tingling, and often a burning heat, were felt in the scalp; sudden detonation in the center of the head apparently; buzzing and singing in the ears, and very constant headache, were also experienced. In the extremities, the tongue, and the genitals, there were felt peculiar tingling, numbness, coldness, creeping, and similar sensations. During the whole time of the existence of his symptoms Mr. — suffered from depression of spirits, a deep melancholy in fact, and he lived in constant apprehension of failure of mind.

Physicians whom he consulted in the West located the malady in the brain, diagnosed cerebral hyperæmia, the prelude to softening.

When Mr. — came to see me, sixteen months ago, the symptoms just detailed continued, and were rather increased than diminished. The objective examination furnished the following details:

His face is full, the eyelids puffy, and the lower lid swollen into a bag; the conjunctivæ are injected, the sclerotic muddy, and the pupil sluggish in movement. On ophthalmoscopic examination, the fundus is seen to be injected, small vessels prominent, veins swollen. There is no optical defect, except that due to his age. The membrani tympani is also rather deeply red, and vessels too small to be seen under ordinary circumstances are now in view. Hearing is unaffected. Motility, sensibility—the tactile, pain and temperature senses—are unaffected; and the reflexes remain normal, although probably a little sluggish. The electrical reactions are normal.

His tongue is heavily coated, the breath foul. His appetite is good, but a sense of fullness at the epigastrium persists for several hours after meals; acidity and eructations of rather foul gas now and then occur. The stools have the normal appearance—consistence, color, and odor. The urine is copious, acid, specific gravity rather high (1,025 to 1,030), and there are traces of sugar, as is usual under such circumstances.

The action of the heart is good, the pulse regular, the tension of the vessel rather high. The respiratory movements and murmurs are normal. The area of hepatic dulness is rather enlarged, and the splenic dulness seems also to be increased.

Subjectively the following symptoms are experienced: Various strange sensations in the scalp; a persistent headache; blurred vision at times; vertiginous feelings occurring irregularly and of varying severity; dependency, vague apprehensions; fear of places, especially of crowded assemblages; difficulty of deciding questions very trivial or otherwise, in place of former promptness; impaired memory for persons, names, and things.

Notwithstanding this extended list of symptoms, Mr. — did not have an ill look, but, on the contrary, on superficial examination, appeared to be robust. To him and to his immediate family the situation seemed in a high degree alarming. The surrender of his position and his business interests was regarded as imminent. To the apprehension awakened by his head symptoms was added the diagnosis of cerebral congestion, and hence the profound melancholy into which he was plunged.

Commentary.—My conclusion was that the disturbances in the functions of the brain and nervous system were secondary to derangement of the assimilative processes—of the primary and secondary assimilation—and that to the functional disorder thus caused are added the effects of introspection, and the realization by the centers of conscious impressions, to an unusual extent, of ordinary peripheral excitations. My reasons for coming to this conclusion will appear hereafter. The remedies consisted in a careful regulation of the diet, in baths, exercise, in a reduction of the hours devoted to work, but not the cessation of work; in the use of a laxative quantity of sodium phosphate daily, and in the administration of the aqueous extract of ergot, with the chloride of gold and sodium, and a minute quantity of bichloride of mercury. If time and space would allow, the details of the hygienic management—so important in these cases—could very profitably, I think, occupy our attention. But I must pass on to the next case.

CASE II.—THE ANÆMIC TYPE.—Mr. —, aged fifty-seven; lawyer by profession. His type of somatic constitution is the nervo-sanguine; weight, 145; height, 5 feet 9 inches. He has immense mental energy, extraordinary quickness of perception, a capital logical and critical faculty, and fine oratorical power. These native abilities, conjoined with extensive cultivation, soon placed him among the foremost men at the bar of the city where he practiced, and have long maintained him in that position. For many years he has been a dyspeptic, and suffered much from eructations of gas, from acidity, and flatulence. At times—months, even years intervening—he has experienced very severe seizures, accompanied by extreme mental depression, alternating with as extreme mental exaltation. During the past five years he has had two attacks of gout, neither severe nor protracted. During the whole course of his professional life he has sustained no reverses, encountered no other anxieties than those of a successful lawyer, and has been rather singularly free, indeed, from the worries of life. Receiving last summer the nomination as a candidate to an important office, this cultivated gentleman, scholar, and lawyer, this man of nice tastes and high tone, entered on a canvass marked by vituperation and slander to an unusual extent. About the same time some business interests became entangled and caused no little worry. During the campaign he visited some malarious districts and spoke several times at night in the open air. A speaker of great readiness and power, he never suffered from any considerable fatigue after public speaking, and hence he was now surprised to find himself exceedingly tired after even a brief effort. He began to have drenching night sweats, lost his appetite, grew weak, and was compelled to return home. It was then ascertained that he had malarial fever, and was treated accordingly. But at this time, and subsequently, symptoms not necessarily of malarial origin appeared. He became frightfully dyspeptic, had enormous eructations of gas, and very considerable flatulence; his arms and legs had a numb feeling, attended

with "pins and needles"; he walked with some difficulty, partly because of weakness; he was somnolent and slept a good deal, and his spirits were extremely depressed, especially on awaking in the morning. During these periods of depression he was so overwhelmed with despondency that he was apprehensive he would lose his self-control entirely.

When he placed himself under my charge, he had still a slight daily paroxysm of fever, the exacerbation occurring in the morning, but this disappeared in a few days under the action of some efficient doses of quinine. He was very weak, pallid, and emaciated, and slept a good deal of the time. He had no headache; his vision was rather dull, and ideas and speech slow. Every morning on awaking he was profoundly melancholic, and all the annoyances which the campaign had developed were gone over in his mind. He could talk of nothing else—think of nothing else than his ill feelings and the disagreeable political and personal slanders of which he had been made the victim. He complained much of the numbness of his hands, of weakness in the limbs; and he talked incessantly of his depressed feelings. The bladder became irritable, and he was compelled to rise every two or three hours during the night, the urine being acid, and depositing heavily of uric acid. Presently the somnolence was displaced by insomnia, and he slept less and less, and rose in the morning haggard, exhausted, and horribly nervous and depressed. Ordinary hypnotics proved unequal to the effort to force sleep, and increasing doses of chloral became necessary. His mental activity, heretofore so remarkable, declined, and the effort to force his mind to the performance of any work, such as letter-writing, caused a sensation of fatigue. He also became undecided, even in small matters, ceased to have any inclination to go out and mingle with the public, and grew more and more averse to political movements. He reached a point finally when to meet strangers caused him great distress, excited the circulation, and induced a cold sweat.

As it became indispensable that he should resume the canvass, he made a strong effort, and, notwithstanding the fatigue, mental and moral depression, and exposure of public speaking, handshaking, and other matters of political expediency, he actually improved somewhat. The insomnia, irritable bladder, and hypochondriasis, however, continued, but to a less degree. In a few weeks, by means chiefly hygienic, I succeeded in stopping the chloral; natural sleep was resumed, although it remained somewhat fitful. Suitable dietetic regulations, baths, exercise, and medicines, *pro re nata*, removed, or at least greatly modified, the principal symptoms. Two weeks at Atlantic City accomplished no little good, and when he returned to Philadelphia last week he appeared to be nearly his old self.

Commentary. In this case we have exhibited that complexus of symptoms entitled neurasthenia or nervous prostration in its anemic form, produced by several factors—moral and somatic. The moral were very influential, but, unless the conditions producing bodily depression had occurred, the former causes could hardly have effected such results. Long-standing dyspepsia had prepared the way; malarial intoxication and fatigue contributed an important series of changes, and upon this weakened bodily state were precipitated crushing moral influences.

These cases, whose histories I have just read, are typical—each is the representative of a group. The causes are complex; the effects are not limited to one organ, or set of organs, but involve the system in general. To name this malady from the disturbance in one system seems to me an error, unless the definition is sufficiently elastic to include all the functions affected. Neurasthenia names one only of the parts involved. To entitle this the "American disease" is a strange misnomer. It might with more propriety be called the "French disease," for a condition known as "the nervous state," as "nervism," as "neurasthenia," and similar terms, has been recognized and frequently described by French writers from an early period in this century. In France have existed the causes in the most influential form. The frequent political convulsions, the exacting social life of the great cities, and the harassing struggle for ex-

istence inseparable from the state of the great mass of the population, induce—if any mere external conditions can—that which is called nervous exhaustion. There are two factors supposed to be especially influential in this country—work, and our exciting political and social life. I believe that the effect of these is greatly overrated.

The brain, of all the organs of the body, illustrates, in the most perfect manner, that which has been happily styled "the principle of least action." That is, to execute given tasks, it expends the least possible force, or, to express the same idea in another form, its work is done with ease, with the minimum of effort. Given a certain amount of repose—sleep—and supplied with proper nutriment—healthy blood—the brain will do its allotted work continuously during its working—the waking—hours. So far from being injured by severe labor carried on under normal conditions, the brain is improved by it. Mental activity, like muscular exercise, keeps the brain in a healthy state. When, therefore, a man says he is suffering from the effects of mental overwork, I want to know what his vices are. Worry may be one of these. Worry is exhausting. The worries of life do infinitely more harm than the work of life, how onerous soever it may be. The cases I have just read illustrate this.

I deny that life is more exciting on this side of the Atlantic. The one prize of life is money, and to get possession of it is the supreme purpose, to the attainment of which every energy is put forth. Is it less so elsewhere? Who are the peoples that despise money, and make no effort to obtain it? Here life is less exciting, because our political condition is stable, and but comparatively little exertion is required to secure a comfortable subsistence. I am speaking now of the mass of the population, and not of the few consumed by ambition for political and social distinction, or led by a pitiless greed. It is the very ease and luxury of our American life that cause mischief. It is the indulgence in eating and drinking, the abuse of alcohol and tobacco, sexual excesses, sedentary habits, and too luxurious lives generally, that induce the state of the system called nervous exhaustion. If I had time, each of these should be considered in relation to this subject. In the first case I narrated, the pleasures of the table and disordered assimilative functions caused the trouble. In the second case, dyspepsia, malarial toxemia, and unusual fatigue were the pathogenic factors. In both, the effects of these causes were increased by moral influences—in one, the anxieties involved in vast business enterprises; in the other, the excitement of a hot political contest. These moral causes would have had no injurious effect had not the somatic conditions been unfavorable.

I come now to the most difficult part of my subject. I have to answer this important question: Why are the somatic derangements caused by the conditions referred to in some cases accompanied by the mental and nervous symptoms which belong to neurasthenia? Why do some subjects with indigestion and assimilative disorders, or with the results of dyspepsia and malaria, suffer from the derangements of the mental and nervous functions, and not others? I might here take refuge behind an accepted generalization, and say that the presence or absence of the neurotic type of constitution explained the difference in the result. There is aptness in this explanation, but it is not entirely adequate. There is a mental condition of great importance, and, unless we comprehend this, we fail to realize all the possibilities of the nervous side of these cases. I, however, barely hint at the main points, under these circumstances. Besides, I wish to avoid a too metaphysical discussion of the subject.

In the conduct of life, every man who has a position to make or to maintain exerts a certain moral force to hold himself up

to his work. Some men are so happily constituted that they are quite unconscious of the effort, and stand in the front, serenely confident. Others are all the time laboring; they feel it and know it, and are like the soldiers of Thomas's corps at the battle of Chickamauga, who, sorely pressed, now and then looked back, to see whether their grim and resolute commander was still behind them with his invincible courage. Men conscious of the effort making to keep up, need but little excuse to surrender themselves to their sensations. At the present time nervous prostration is much feared; its symptomatology is a common subject of discussion; and hence, familiar with its character, the imagination of a man who is arrested in his career by some of the ailments supposed to belong to it readily supplies the rest. When a man begins the study of his bodily sensations, having a certain model in his mind, he has little difficulty in filling out the details. All the world knows that when the attention is strongly fixed on an organ of the body, functional disturbances of it ensue, and finally structural changes may be induced. No part of the body is without sensation, even in health. To perceive these sensations the attention needs to be withdrawn from external things and concentrated on the part. Thus it is when the subject of neurasthenia pursues his introspection; he becomes conscious of numerous sensations, which, because now felt for the first time, are new. Under these circumstances, also, the seat of conscious impressions becomes more acutely perceptive. Suggestion adds its quota of symptoms.

To the indefinite and multiplying nervous symptoms developing thus subjectively must be added the reflex. Headache, vertigo, *tinnitus aurium*, amaurosis, diplopia, hallucinations and illusions, defects of speech, paralysis, are reflex symptoms on the part of the brain; palpitation, intermittent pulse, angina pectoris, laryngismus stridulus, asthma, are among the reflexes of the respiratory organs and heart; neuralgia, anesthesia, and other disorders of the sensory nerves, and local paralysis, affections of the motor nerves, included among the nerve reflexes, may all be dependent on reflex excitations proceeding from the stomach. Indeed, there is no symptom in Beard's catalogue of those belonging to neurasthenia that may not be due to merely reflex influences having their initial seat in the digestive apparatus. It follows that the term neurasthenia, or its common equivalent, nervous prostration, is either inadequate, or it expresses too much. Inadequate if the complex of symptoms includes the functional disturbances of all the organs affected, expresses too much if the malady is a merely nervous one.

In reply to the question, "What is meant by nervous prostration?" I respond, "A disease usually functional, situated in one or more organs, during the course of which reflex disturbances of the brain occur, and numerous subjective sensations in all parts of the body are realized by the consciousness."

I deny that neurasthenia is a primary nervous affection, or that it is a substantive disease. I hold that it is symptomatic and secondary.

This conception fixed in the mind, the treatment of neurasthenia is successful or unsuccessful according to the measure of our skill in localizing the initial disturbance, and in addressing our remedies to that as well as to the general state.

Dr. MILLS, in opening the discussion, by request of the Chair, said: I understand that Dr. Bartholow denies that a disease exists primarily nervous in origin which can be called neurasthenia. He classes all cases so called under two heads, congestive and anemic, and holds that the symptoms presented are chiefly reflex effects of digestive or other visceral troubles. I have no doubt that many cases are to be thus explained, but we have others in which the cerebral condition is primary. In cases with the symptoms as detailed in the paper, we may perhaps clearly ascribe them to the causes and conditions referred

to by Dr. Bartholow, but other cases may be explained in a different manner.

In individuals whose higher ganglionic centers are so constituted, from bad inheritance or poor training, or both, that they can not bear much strain, when subjected to this strain, these centers exhaust. We have certain functions called organic functions, respiration, vaso-motor action, etc., with centers in medulla oblongata and spinal cord. These functions must be maintained as long as the individual exists. Their centers must be nourished and sustained in a uniform way. Presiding over automatic movements, they must be kept in the highest tone, must have good blood and plenty of it. It is a principle brought out in the paper that local diversion of blood to any one organ or part will take it from other organs or parts; and we may, in accordance with this, have the higher brain diverting blood from the lower, or lower brain from the higher. We have *nervous* symptoms, the result of this over-strain of nerve-centers, and the disturbance of the equilibrium of the circulation, thereby brought about.

I am inclined to differ from Dr. Bartholow, and agree with Dr. Beard as to the propriety of the term "American disease." The social and business exigencies in this country are different, are more taxing than in Europe. In England, for instance, men become mature and enter public life at later periods than here. In France the difference is not so great, but the more absolute division of society into grades and castes prevents too fierce a struggle for high position. Here every man has the chance to rise to the highest position, and men enter especially political life in youth. Americans are not trained for special lines of life-work. They often attempt work too high for their mental powers and break down.

Dr. TYSON: I have many times asked myself the question, "What is nervous prostration?" The answer was always, "It is not a nervous disease, certainly not an organic nervous disease, and probably not a functional one. It is rather a condition of muscular fatigue, and it may be nervous fatigue. Most of the cases are accompanied by digestive derangements, which are responsible for many of the symptoms, most of which are reflex." At the same time, I admit that some of the symptoms are puzzling, and not easily explained. Among these is the pain in the back of the head, often referred to as the result of "nerve tire," and sometimes regarded as an important indication of cerebral disorder, which it is not. In women, uterine derangement is often responsible for the complex symptoms known as nervous prostration.

The point, however, that attracted me in the paper read was allusion to the condition of the urine in one of the cases. It was described as dark brown, of high specific gravity, containing a trace of sugar. I have seen such cases, and think it not unlikely that the apparent sugar reaction is really due to uric acid, which is often abundantly present in these urines of deranged digestion. If we get rid of the excess of uric acid by allowing it to precipitate spontaneously, or precipitate it by the addition of an acid, the sugar reaction with the copper tests does not take place. Other characters of the urine, particularly its dark color and scantiness, are not usual to sugar-containing urine.

Dr. ESKRIDGE: The most important point in the subject is whether the condition called neurasthenia is primarily a nervous disorder, or a disturbance in other parts of the body. I would have been better pleased if Dr. Mills had elaborated more thoroughly his statements as to the organic functions. He said these functions must be well nourished, and that failure in them is due to failure in the upper nervous system. I would have liked if he had gone further in his explanation. Is this failure due to disturbance in the brain and upper portion of

spinal cord primarily, or to failure in other parts of the body? Those who have paid attention to this subject say that breakdown does not occur unconnected with either worry or vice. I have never seen a case from mental over-work alone. In five cases of neurasthenia of which I have notes, one was from sexual excess; two from worry connected with family troubles; another from alcoholic excess, with sexual vices; and the fifth from sunstroke, followed by sexual over-indulgences. In the last case it seemed as if the brain was primarily at fault. It appears to me that nervous prostration, so called, is a depressed condition of the whole system, the trouble manifesting itself as a general nervous condition secondarily, after organs other than the brain have been primarily affected. The therapeutics also favor this view, because the cases are benefited, not by agents addressed to the nervous system alone, but by hygienic and tonic measures.

Dr. GLASGOW: I have come to regard these cases as not nervous in origin, but as largely due to digestive troubles. They are cured by attention to the disordered functions. I have known a short residence in Atlantic City, without any medical treatment, to suffice for a cure.

Dr. BARTHOLOW, in closing the discussion, said: The great question is, Is neurasthenia functional, or does it arise from organic change in the nervous system? I maintain that it is largely reflex, and frequently from gastric disturbance. Neurasthenia in women is associated with an anemic condition and ovarian and uterine disorders. They are pale and weak, and, if they are subjected to any moral or mental trouble, give way; but, if they are well nourished, sustain any kind of shocks without suffering in health.

In regard to the term "American disease," and to the claim that the peculiar conditions of American life are causative of neurasthenia, it will suffice to say that in some of the European states a higher grade of education is maintained than in this country. In Prussia, for instance, every one is taught to read; education is more general than in Massachusetts. The struggle to maintain existence, and hence the demands on the brain, are severer than here, and, although neurasthenia is said to be uncommon, there are diseases similar to that called nervous exhaustion in this country, arising from similar causes.

Worry has been mentioned as a cause of nervous exhaustion; now, worry hurts a man just in proportion to his condition. If he is in good health, or phlegmatic in temperament, the worry may be well borne, but, if he is out of health, worry will have a powerful effect on the nervous system. I do not deny that various causes may produce brain disease, but I deny that the so-called neurasthenia is due to an organic lesion of the nervous system. I maintain that it is part of a morbid complexus; a reflex condition, in large part, of maladies situated in the stomach, the liver, the uterus, or other organs.

(To be concluded.)

Miscellany.

TRACHEOTOMY NOTES.—*Associating Unmistakenly.* An important discovery seems to have been made by Mr. Harold Senior, of the London Chemical Society, to judge from an abstract given in a recent number of the "Lancet" of a paper read by him at a meeting of the Pharmaceutical Society. It amounts to nothing less than that crotonoil may be separated into two different oils by the action of alcohol, one of which is irritating but not purgative, and the other purgative but not irritating. When alcohol of the specific gravity of 0.794 to 0.800 is

added to croton oil in the proportion of seven or more volumes to six, the oil separates into two parts—one of them (the vesicating oil) dissolves in the alcohol, and remains soluble in alcohol in all proportions; the other (the purgative oil) separates, and is then found to have become insoluble in any proportion of alcohol. This insoluble oil is said to be a safe and pleasant purgative, free from any undesirable action, in doses of one tenth to one half a minim, in the form of pills made with magnesium carbonate and extract of henbane as excipients.

Papaïne (Vegetable Pepsin).—Dr. Berthaud advocates ("L'union médicale," November 13, 1883) a vegetable substance called "papaïne" as a substitute for pepsin. Papaïne is a milky juice extracted from the trunk and green fruit of the *Caraca papaya*. This valuable tree is indigenous, according to some, to South America; according to others, to the Spice Islands. It is found in India, in the Mauritius Island, in the Antilles, and in South America. The juice which exudes from the green fruit of the papaya, and even the seeds of this tree, possess valuable vermifuge properties. But the tree is chiefly interesting from the fact that the juice obtained from its fruit, leaves, and trunk contains a considerable proportion of a principle analogous to animal pepsin, to which M. Wurz and M. Bouchut have applied the name "vegetable pepsin." This juice exercises a marked action on muscular fiber, causing its speedy softening and digestion. Even the emanations from the tree are sufficient to produce this singular action on meat. In the countries where the papaya is cultivated the inhabitants suspend in the high branches the meats which they wish to make tender. It is therefore not strange that the idea should arise of making the papaya juice subserve some practical use to mankind. Experiments have yielded the most satisfactory results. M. Wurz, in a report to the Paris Academy of Sciences, in November, 1880, stated that papaïne had dissolved a thousand times its own weight of fibrin, acting with as much rapidity and regularity as animal pepsin. It has been tested clinically as well as in the laboratory, and abundant evidence has been afforded that its action is certain and constant. Its general use would, therefore, prove more satisfactory than that of animal pepsin, much of which, as it is now found in commerce, is comparatively worthless from adulterations. Moreover, according to M. Wurz and M. Bouchut, all nitrogenous foods—milk, flesh, fibrin—are digested in much larger quantity by papaya juice than by pepsin secreted by the stomach; furthermore, the vegetable ferment possesses this great advantage over the animal ferment, that it acts equally well whether in acid, neutral, or alkaline solutions.

Papaïne is indicated in cases of gastralgia, gastritis, dyspepsia, and all affections characterized by perverted functional action of the stomach. In all such cases it is (according to the opinion of Dr. Berthaud) a much more valuable remedy than animal pepsin.

Note on Hyoscyamine.—Dr. R. A. Hayes, of Dublin, Ireland, reports ("Dublin Journal of Medical Science," December, 1883) a case of tremor of the left arm which he treated with hyoscyamine. The patient, when he came under Dr. Hayes's care, had been troubled with this tremor for six months. Eighteen months before it came on he had suffered an injury of the shoulder of the same side. He was given one sixteenth of a grain of hyoscyamine in pill. A single dose daily for two days produced no effect on the tremor. Next day two doses, morning and evening, relieved the tremor in some measure. The following morning a dose of one eighth of a grain was given. Delirium soon supervened, and continued through the day, but the tremor ceased. The next morning one sixteenth of a grain was followed by delirium, which did not completely pass off until the following day; but the tremor was decidedly controlled. The drug was now discontinued, it having completely paralyzed the patient's accommodation and interfered seriously with his sleep. The tremor returned at once, and soon became very marked. Three days afterward the hyoscyamine was resumed in doses of one thirty-second of a grain three times a day. In two days the tremor was lessened; in six days the ciliary muscle had again become paralyzed, and the medicine was stopped at the patient's request, though the tremor was much relieved. The smaller doses, while they did not affect the pupils, paralyzed the accommodation so completely that reading was impossible. It should be stated, however, that, when the administration of hyoscyamine was begun, the patient's eyes had not recovered from the effects of atropine, which had been used to facilitate an ophthalmoscopic examination.

Lectures and Addresses.

LECTURES ON DISEASES OF THE KIDNEYS, DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS.

BY FRANCIS DELAFIELD, M.D.,
PROFESSOR OF PATHOLOGY AND PRACTICAL MEDICINE.

LECTURE VI.

Acute Diffuse Nephritis (continued).

GENTLEMEN: I was speaking to you yesterday of acute diffuse nephritis, and I called your attention to the fact that there were two different classes of cases characterized by different clinical histories. I told you that in the first group of cases the invasion of the disease was usually acute and the symptoms were developed rapidly, and at the same time there was a marked febrile movement.

We now come to the second group of cases of acute diffuse nephritis. In this set the invasion of the disease is not usually acute and well marked, but it is slow and gradual. There are no rigors and no febrile movement, and very often the patient can not tell you the precise day on which the symptoms commenced, for they have begun slowly and gradually, and have increased steadily. In most cases the patients will tell you that they suddenly found they were beginning to lose their appetites and to be troubled with nausea, and some of them with vomiting also, though this is not a constant symptom. They then began to have pain in the back, of moderate intensity, and referred to the lumbar region. This, however, is always a very unreliable symptom, for perhaps half of all patients suffering from any of the ordinary diseases will tell you at some time that they have pain in the back. It is a very common symptom indeed. These patients find also that there is a loss of bodily strength and muscular force, and an indisposition to either muscular or mental exertion, and they do not feel in their ordinary mental or bodily condition. Then they notice, sometimes, at first, or in some cases not until after some time, that their urine is beginning to be diminished in amount, but this diminution does not usually reach any great degree. The patients pass, perhaps, twelve, or fourteen, or sixteen ounces in the twenty-four hours. This urine may be natural in color and appearance, or it may be changed somewhat by the addition of a certain amount of blood. When we come to examine the urine we find that its specific gravity is low, although it is diminished in amount. Albumin is present in large amount, and we also find all sorts of casts present in very considerable numbers.

Dropsy is developed very early in the disease, and it regularly reaches a very considerable degree. If it is confined to the legs, they will become very much swollen, or it may involve the subcutaneous connective tissue throughout the body, and any of the serous cavities besides. The dropsy, then, is the most marked symptom in this class of cases.

Cerebral symptoms are generally almost altogether absent, or they reach no great degree of development. There may be some dyspnoea, but this is not excessive. The color of the patient changes, and the skin and mucous membranes become pale, and this is accompanied by a change in the composition of the blood.

These symptoms may all be developed during the course of a few weeks, and after this they last sometimes for weeks, and sometimes for several months. Then, after this condition has persisted for a number of weeks or months, there may be a gradual improvement in the condition of the patient: the appetite returns, the dropsy diminishes in amount, the urine increases in quantity, the albumin becomes less marked, the casts are less and less numerous, and the patient continues to improve until the dropsy has disappeared and he is able to be out and to go about again. But the anæmia does not disappear at once, but continues for some time after, and there will also be still a moderate amount of albumin and a few casts in the urine. Then, after a still longer time, these symptoms disappear also, and the patient is restored to his natural health.

But in other cases the course of the disease is not so favorable, for it continues to advance and becomes chronic, and then the patients go on and have the symptoms and lesions of chronic diffuse nephritis. This continuance of the disease is often separated from the more acute stage by a sort of interval. That is, the patients first have the ordinary symptoms of acute diffuse nephritis of this particular variety, then, after a time, they get better, the dropsy disappears, and they only complain of feeling a little weak. But some albumin and a few casts usually remain in the urine. In other cases there seems to be an absolute recovery. This freedom from symptoms lasts for several months, perhaps, then the old symptoms come back again, the dropsy, the disturbances of the stomach, and the anæmia, all return and do not disappear again, but go on getting constantly worse and worse, until the patient finally dies at the end of several months. On examining the kidneys of such a patient, you do not find the changes of a simple form of acute diffuse nephritis, but they look rather as if they had originally been the seat of an acute diffuse nephritis which had afterward become chronic. So, after an apparent recovery, you must not be in too much of a hurry to dismiss these patients from your observation, for the symptoms may return after they have been absent for a number of months. Most of the examples of this form terminate in one of two ways—either they end in recovery, or else they pass on into the chronic condition.

The treatment of this group of cases is mainly directed toward diminishing the dropsy, and we may attempt to do this in the same way as in cases of acute parenchymatous nephritis. We may try the effects of cathartics and diuretics, and of sweating the patient, and see if by these means the amount of urine is increased and the dropsy diminished. If no effect is produced within a few days, then stop the treatment and wait a while, then try again, and, when the proper time has arrived, the remedies will act, the urine will increase, and the dropsy diminish or disappear.

Then we have to attend to feeding the patient and to improving the condition of the blood in practically the same way as in acute parenchymatous nephritis. You will observe I have presented to you the symptoms of this set of cases of acute diffuse nephritis as the same as the symptoms of acute parenchymatous nephritis, and it must be confessed that in a large number of cases, during life, we can not distinguish between these two diseases, for the symptoms are the same. Therefore the treatment is the same, and there is very much the same prognosis.

A considerable number of cases of acute diffuse nephritis occur in the course of *scarlet fever*, and thus become a complication of it. But you must remember that, with scarlet fever, acute parenchymatous nephritis is also a common complication. So, when you use the term "scarlatinal nephritis," you must do so remembering that there are these two forms of nephritis which may complicate a scarlet fever, an acute parenchymatous and an acute diffuse inflammation of the kidneys. There are apparently but very few cases of scarlet fever that run their course without the presence of either one or the other of these two forms of renal disease as a complication, and acute parenchymatous nephritis is the more common one, while the acute diffuse inflammation is the less common. There are also some cases of scarlet fever that run their regular course throughout, and you would never suppose that there was any accompanying disease of the kidneys if you did not examine the urine. But yet, when you do examine it, you find some albumin and a few casts, which are evidence of a parenchymatous inflammation. When, however, a diffuse nephritis is present, it does give symptoms, and there are not only changes in the urine, but also constitutional symptoms, varying in severity in different cases.

The precise time in the course of the scarlet fever at which the kidney lesion is developed varies a good deal in different cases, and we are unable to determine this just as we are unable to diagnosticate between cases of parenchymatous and diffuse nephritis. The larger number of these renal complications do not result in the death of the patient, and, as only a moderate number die, we can not determine very often the exact nature of the renal disease. Taking these two sets of cases together, however, it is found that the renal symptoms may make their appearance at any period between the first day of the scarlet fever and the ninth week after the invasion. But the great majority of cases occur on or about the fourteenth day of the scarlet fever, and next in frequency comes the twenty-first day, and next the seventh day. So, if we take all the cases of scarlet fever complicated with renal disease together, in most of them we shall find that the kidney complication is developed either at the fourteenth, the twenty-first, or the seventh day, and the most frequent of these is about the fourteenth day.

These patients give us first the ordinary symptoms of scarlet fever, sometimes severe in form and sometimes mild, for this complication seems to be as apt to occur with mild as with the severe cases of scarlet fever; and then, after the ordinary symptoms of the scarlet fever have lasted it may be for one, two, or three weeks or more, there is noticed a change in the condition of the patient—he is evidently

worse, and a loss of appetite makes itself evident. If the renal disease is not developed until the fourteenth or twenty-first day, then very likely the patient will be feeling better of the scarlet fever, when suddenly rigors appear, and then, if the appetite has returned with the improvement in the scarlet fever, it will now be lost again, and there may be added more or less nausea and perhaps vomiting. In many cases there will at this time be developed a new febrile movement, and, if the fever of the scarlet fever is still continuing, it becomes higher than before, while if it has already reached the normal there will now be an increase of temperature, but the new febrile movement will not be of any great degree of severity. The patients will now begin to complain of pain in the back, and they will become fretful and restless and be unable to sleep well at night, and between these periods of restlessness and sleeplessness they will be unnaturally dull and stupid, and, if it is a grown-up person or a pretty old child, he will complain of headache. In bad cases there may be developed delirium, convulsions, and a very marked stupor, which may go on to complete unconsciousness.

Dropsy is developed, sometimes only to a very moderate extent, and sometimes there is very marked general anasarca. There are the ordinary changes in the blood, and the patient's appearance becomes anæmic. The urine is scanty or absolutely suppressed, it has a low specific gravity and contains some blood, and albumin is present in large amount, and there are numerous casts.

These symptoms, when once developed, last, in most cases, about two weeks, then all the symptoms begin to diminish, and finally they disappear altogether. The changes in the urine, however, continue for a considerable time after the patient has apparently entirely recovered.

The prognosis in most of these cases of nephritis complicating scarlet fever is good, and the patients get better usually after the second week. But sometimes the renal complication will be more severe in character, and prove fatal either at the end of a few days, or perhaps at the end of two or three weeks. Then in still other cases the acute kidney lesion changes into a chronic lesion, and it goes on and develops into a chronic diffuse nephritis.

As regards the treatment of these cases of scarlatinal nephritis, we find that some of them hardly require any treatment at all. The urine is not very much diminished and the symptoms are not very intense, and all that is necessary is to keep the child in bed and keep the bowels open with some simple laxative, and give it only a fluid diet, and then wait quietly for the symptoms to subside. But, in case the symptoms are more severe, it may be necessary to interfere, and we may apply cups or hot fomentations over the lumbar region, or sweat the patient and give more vigorous cathartics, and in some cases it is also necessary to give opium to quiet the extreme restlessness and sleeplessness. Then, when the symptoms subside, if the patient is pretty well nourished, no further treatment is necessary, but there may be a gradual return to animal food, and the opium may be withheld. But, if the patient is not in good condition, then you must look after the general nutrition, and try to improve the condition of the blood in the ordinary way.

Original Communications.

THE DANGER OF
LARGE DOSES OF QUININE.*

By A. A. SMITH, M. D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF CLINICAL MEDICINE, IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

Is the use of quinine in large doses ever dangerous in hyperpyrexia with tendency to heart failure?

In order that I may not be charged with prejudice in regard to the use of quinine, let me say at the outset: I place it second in importance only to opium, in our armamentarium of drugs, in the treatment of diseases in this region.

It will be admitted that one of the most serious dangers to be apprehended in any disease in which high temperature prevails for a few days is the so-called heart failure. Many observers contend that this heart failure is due to the direct effect of the great heat on the heart muscular tissue, producing in many cases a permanent degeneration, in others a temporary enfeeblement. Other observers consider it due to depression of nerve force, and that no degeneration of heart muscular tissue occurs. It is possible both views are correct. In some cases it may be through the nervous system; in others, and it seems to me the more rare condition, muscular degeneration may occur. If real muscular degeneration does occur, there ought to remain, even if the patient recovers from his attack of fever, permanent enfeeblement of the heart. Whether through the one system or the other, it is of serious import to the patient, for in many cases death is directly traceable to this heart failure.

As the two types of fever, typhoid may represent the fevers of long duration, and pneumonia those of short duration.

During the first few days, usually, of a typical acute lobar pneumonia, there is an increased rapidity of pulse; it is full and bounding and non-compressible; the first sound of the heart is intensified; there is some cerebral excitement, probably due, in a measure, to the increased vascular excitement. After the first three days, the pulse in severe cases increases in rapidity, but usually diminishes in force, and the first sound of the heart is diminished in intensity. These signs are usually regarded as evidences of exhaustion. The fatal result occurs in many cases on the fourth, fifth, or sixth day. From the third to the sixth day may be regarded as the dangerous days, as the rule. In typhoid fever, the disease goes on developing up to the sixth, to the tenth day, and then there begin those evidences of heart failure as shown by the increased rapidity of pulse and diminution in its force, and decreasing intensity of the first sound of the heart. These descriptions give a general idea of the progress of these two diseases so far as the heart is concerned. There are, of course, many exceptions to the rule as stated above. Cases do occur with the progress as here stated, and will answer our purpose in the discussion of the question.

Almost all observers agree that when quinine is given as an antipyretic it should be given in one single large dose, or at least a large quantity must be given within an hour. Usually this need not be repeated within twenty-four hours. Others give the large doses at twelve hours' interval. A large dose may be anywhere from twenty to sixty grains, depending somewhat on the observer and somewhat on the height to which the temperature has risen.

The physiological effect of quinine on the circulatory system is a subject of great interest, and especially so to us to-night, in view of the question for discussion.

Almost all observers agree that small doses of quinine, say from two to five grains, stimulate the heart both as to frequency and force.

Almost all observers agree that large doses act, in many cases, as powerful antipyretics. Some even attempt to explain their antipyretic effects by their influence as an arterial and cardiac sedative. I will not enter into any discussion as to how quinine acts as an antipyretic; its effect on the heart, directly or indirectly, is what concerns us in the discussion to-night. The effects of quinine on the circulation may be studied from two standpoints—that of the experimentalist and that of the clinician. I admit that many experiments may lose much of their value from the fact that the observer makes his experiments under the influence of a very strong dominant idea. Therefore great care should be shown in estimating the value of any experiments.

The experiments of Eulenbourg and other observers seem to show that quinine in sufficient quantity causes a diastolic cardiac arrest by a direct depressant action on the heart. Other experiments seem to show that toxic doses of quinine paralyze the vaso-motor nervous system.

Binz's experiments seem to show that some of the disturbances of sight and hearing depend on impairment of the heart's function. He thinks experiments on warm-blooded animals have proved that the injury to the heart and paralysis of the respiratory center are the cause of death.

Bartholow thinks that quinine in large doses depresses the action of the heart, diminishes the blood-pressure, and enfeebles while it slows the pulse.

Farquharson says large doses of quinine cause the rate of the pulsations to fall, and the arterial tension to diminish, and adds that death may even ensue from convulsions or sudden collapse, following depression of the heart's action.

H. C. Wood, Jr., says: "Quinine, when given in large doses, acts as a powerful depressant, and for this reason is given in some diseases where such action is desired." Many observers have noticed that large doses (some specifying from thirty to sixty grains) produce in man a less frequency and less force of the pulse. Sometimes after very large doses it has been observed that the radial pulse was almost imperceptible. When it became as feeble as this, it was rapid and sometimes irregular. I have frequently observed, even after twenty grains of quinine, that, although while the patient was in a recumbent posture very little change in the frequency of the pulse was noticed, yet when the patient got up and walked about, even leisurely, there was decided increase in the rapidity of the pulse, and some diminishing of its force.

* Read before the New York Clinical Society, November 23, 1883.

The pallor of countenance, with coolness of lips and skin and coldness of extremities, which sometimes follows large doses of quinine, seems to me to be due to depression of the heart's action or a depression of the circulation through the vaso-motor nervous system.

In some patients there is a great susceptibility to the influence of quinine, and frequently "fluttering" at the pit of the stomach and over the præcordial region, with coldness of hands and feet, is complained of.

A gentleman in this city, past sixty years of age, who was formerly in the habit of taking considerable quinine—sometimes as much as thirty grains a day—has told me that after he has taken a quantity above twenty grains a day he has noticed a decided dyspnoea on exercise, fluttering over his præcordial region, a less forcible pulse, and sometimes an irregular one.

I have in a number of instances noticed patients, to whom I have been giving large doses of quinine to reduce temperature, have the temperature suddenly fall, while they passed into a condition of exhaustion with profuse perspiration, feeble pulse, cold hands and feet, and sighing respiration.

I have for some years felt that, if the physiological effects as above described are correct, there comes a time in almost all febrile conditions when quinine *may* be dangerous. This time is when the heart begins to fail, and this usually occurs from the third to the sixth day in pneumonia, and during the second week in typhoid fever, taking these again merely as types of fevers of short and long duration. The temperature after heart failure begins may be as high as or even higher than before, certainly a very important fact in view of the foregoing statements, and in view of the almost routine practice of prescribing large doses of quinine in high temperature, whatever the condition of the heart may be.

Large doses of quinine begin their effects in from a half-hour to two hours. They reach their maximum effects in from four to six hours. Agents can be given to counteract the effects of large doses of quinine on the heart, and should always be given where there is the tendency to heart failure. When they are given, their effects should be kept up for many hours. The effects of some of the cardiac stimulants pass off in a short time. The remedy must be given in such a way that its effects will be kept up continuously. If a single large dose of quinine is given, it would be practically useless, for instance, to give a single dose of ammonia to counteract the distressing effects of the quinine. It must be given in doses repeated every two or three hours, and kept up even after the effects of the quinine have passed off. Almost any of the cardiac stimulants will aid in counteracting the effects of these large doses of quinine; but I have found small doses of opium answer the best purpose. In doses of from a quarter to a half grain, opium is a cardiac stimulant, besides being, under conditions of high temperature, a great sedative to the nerve perturbation which accompanies such a condition.

My observations have led me to the following conclusions, although I am still open to conviction:

Large doses of quinine should not be given in any case

of high temperature after heart failure begins, unless agents to counteract their effects on the heart are given.

Great caution should be exercised in giving large doses of quinine, in high temperature, in any case of organic heart disease with enfeebled power. They should be used cautiously in old people with high temperatures.

I am well aware of the popular prejudice against quinine, and have hesitated somewhat in calling attention to some of the points involved in this question, because there are so many conditions which can be relieved by quinine better than by any other agent. Indeed, I can only repeat what I said at the beginning of this discussion—I place it second in importance only to opium in the treatment of disease in this region.

THREE CASES

ILLUSTRATING THE OCCASIONAL ACTION OF LARGE DOSES OF QUININE.*

By J. WILLISTON WRIGHT, M. D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY
OF THE CITY OF NEW YORK.

CASE I.—*Catarrhal Pneumonia following Measles*.—L. B., ten years old, was first seen April 26, 1876. For the first five days the temperature was 105° F.; the pulse 136 to 140, weak; the respirations 40 to 50. On the seventh day the temperature fell to 98°, the pulse to 90, and the respirations to 30. On the evening of the same day the temperature rose to 103.2°, the pulse to 120, and the respirations to 42. On the eighth day the temperature fell to 102°, the pulse to 98, and the respirations to 40. On the evening of the ninth day the temperature rose to 103.8°, the pulse to 100, and the respirations to 52.

During the next twelve hours, owing to a mistake on the part of the mother in carrying out the directions, the child had twenty-five grains of sulphate of quinine by the mouth and twenty-five grains by the rectum—fifty grains in all. Within two hours of its administration, or on the morning of the tenth day, I found the child in collapse, with a temperature of 98.9°; the pulse 60, very weak and intermittent; and the respirations 32, shallow, sighing, and gasping. The face and lips were cyanosed, and the surface was cold and covered with moisture.

Under the use of large doses of stimulants, external heat, sinapisms, etc., the temperature rose slowly, and on the morning of the eleventh day had reached 96.5°. On the same evening it was 98°, and on the morning of the twelfth day, or sixty hours after the administration of the quinine, it was 98.5°. The patient recovered fully.

CASE II.—*Physo-malarial Fever complicated, in the Third Week, with Broncho-pneumonia, due to Exposure*.—John M., twenty-eight years old, had a temperature of 104° to 105° for five days after the pneumonia began. During this time he took three grains of quinine every three hours, with no appreciable effect on the temperature. On the evening of the fifth day, the temperature being 105°, he took fifteen grains of quinine in one dose, and the same amount on the morning of the sixth day—thirty grains in all. I saw him at 11 A. M. The skin was cold; the face and lips were cyanotic; the temperature was 96°; the pulse 132, feeble and irregular; the respiration sighing; he complained of dyspnoea, and thought he was about to die. Under the use of stimulants, etc., the tempera-

* Being a communication addressed to Dr. A. A. Smith, and read by him before the New York Clinical Society, December 28, 1883.

ture rose gradually, and at the end of twenty-four hours had reached 102.5°. He eventually recovered.

CASE III.—Acute Catarrhal Phthisis following Pneumonia.—F. N., twenty-four years old, frequently had a temperature of 103.5° to 104° for several days together. On several of these occasions doses of twenty to thirty grains of quinine were given, with the hope of reducing the temperature. The temperature was generally unaffected by the remedy until after the symptoms of shock came on, when it became sub-normal, and remained so until the effects of the quinine had passed off. The face and lips were usually cyanotic, the heart's action was feeble and irregular, and the patient complained of dyspnoea with extreme prostration.

The accompanying chart shows the course of the temperature, pulse, and respirations in Case I.

I could give you notes of several other cases if it were necessary, but the story is about the same in all.

A CASE OF POISONING BY SULPHATE OF CINCHONIDINE.

By JOSEPH E. WINTERS, M.D.,

CLINICAL LECTURER ON DISEASES OF CHILDREN IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

A boy of about five years of age appeared at my clinic in the early part of May last, accompanied by his mother, who said to me that he had "the fever" again. I had treated this boy and other members of the same family repeatedly for various manifestations of ague. In January I had attended the boy during a severe attack of remittent fever, from which he made a good recovery under the use of sulphate of cinchonidine.

The afternoon that he came to me his temperature was 103.9° F. His spleen was enlarged, and he was very cachectic. He had the usual symptoms of ague: pain at the pit of the stomach and vomiting. He also complained of headache. His mother said that he had had fever in the afternoon and night for two days previous; that in the mornings of the same days he seemed quite well. A diagnosis of remittent fever was made, and he was ordered eight grains of sulphate of cinchonidine, in solution, every two hours, until either the fever subsided or the skin became moist.

The mother was given a two-ounce solution of sulphate of cinchonidine, which contained eight grains to the drachm. This was at 3 P. M. At ten o'clock the same evening I was asked to see the boy at the house. On arriving at the house, I learned that he had had three convulsions, in which the movements were general, but irregular. There were no convulsive movements when I saw the boy, who was lying on the sofa, apparently exhausted. His temperature was 94.6°; the pulse almost imperceptible at the wrist—in fact, but few radial pulsations could be perceived. In endeavoring to count the cardiac pulsations by auscultation, I made them about seventy-four to the minute. The skin and mucous surfaces appeared utterly bloodless; the pupils were dilated, and the child was semi-conscious. His lack of mental clearness seemed more due to bloodlessness of the brain, if one could judge, than to any other pathological condition.

The child was given his first dose of cinchonidine at three o'clock, when, by mistake, a tablespoonful was given instead of a teaspoonful dose, which was repeated every two hours until two ounces had been administered; so that, within six hours, the boy was given one hundred and twenty-eight grains of sulphate of cinchonidine in solution. None of the medicine was vomited. The boy's bowels had been in proper condition previous to and on this day. His urine was analyzed at the time, and nothing abnormal was discovered in it.

Stimulants were administered; heat and friction were applied to the surface and to the extremities. The boy remained in much the same condition, sank gradually, and died, apparently of exhaustion, at five o'clock the following morning. He was conscious up to the time of death. There were no more convulsions.

Autopsy, twenty-six hours after death.—The sinuses of the brain were filled with dark, slightly coagulated blood. There was no thrombosis of any sinus. The brain was anemic throughout its entire extent. The left heart was contracted, not firmly, and was empty; the right heart contained a small quantity of dark-colored blood. The spleen extended about one inch below the free border of the ribs, and was somewhat enlarged in all directions. It was unnaturally firm, and its capsule was considerably thickened. All the other organs of the body were healthy.

It will be seen that the patient had been treated for the same disease before by means of cinchonidine, on which occasion it had a good effect. The fatal termination on the last occasion was evidently due to poisoning by the drug.

THE RELATIONS OF A PHYSICIAN TO THE COMMONWEALTH.*

By E. C. HARWOOD, M. D.

(Concluded from page 68.)

General Rules for Medical Witnesses.

As medical men are liable to be called upon at any time, either as experts or witnesses, no one should be without some knowledge of medical jurisprudence. In the practice of almost every physician cases will arise connected in some way with the law, or whose results may demand *medico-legal* investigation. He may at any time be called upon to give evidence as to matters which he has never deemed as of the slightest importance, and yet which may involve an innocent or guilty person in serious consequences. Some knowledge of what is required of witnesses in such cases and a slight acquaintance with medico-legal knowledge may enable him to avoid mistakes which may greatly injure his own reputation.

No matter how great a physician's reputation may be, in the particular case or branch of medicine in which he is called upon to testify he will be required to give a careful and concise statement of the grounds on which he bases an opinion, and, if the case is one which has come under his personal observation, he must state all its facts, symptoms, and circumstances. His first care, therefore, should be to cultivate a faculty of minute observation of medical and moral circumstances. In the examination of a body of a person who has died a violent death, he should notice its general condition and position, and, if death has resulted from the effect of wounds, the locality of the wound, its size, form, and direction, the size and position of the weapon, and all circumstances having the slightest relation to the wound should be accurately noted. All blood stains, and all marks on the furniture or on the body, should also be carefully observed.

In all cases where a physician will be likely to be called upon in the future to give evidence, he will find it very convenient to draw up a report or memorandum of facts and appearances while they are fresh in his recollection.

These facts and appearances are generally so minute and detailed that they can not safely be intrusted to the memory.

The witness may refer to such memorandum in order to refresh or assist his memory, even in the witness-box.

A medical witness should be well prepared to give evidence on all parts of the subject of inquiry, and should remember that in all cases there are astute counsel watching for an opportunity to find something in his testimony which may be incorrect, evasive, or confused.

Counsel in the trial of a case are generally well prepared to put questions which may prove puzzling to the witness, particularly when he is not permitted to give an explanation of the grounds on which he forms his opinion.

The various modes of treatment, the causes and effects of certain symptoms, the various schools of medicine, may be gone into by counsel, and a short and, in many cases, a categorical answer will be required.

The subject, therefore, should first be clear in the mind of the witness, in order that his account may not be confused or unsatisfactory.

The case should be carefully considered and viewed from different aspects, and, if an opinion be formed, it should be subjected to criticism and dealt with as if it were that of an adversary. Opinions should not be formed or expressed unless carefully considered, as they may be of the greatest influence upon the fate of the prisoner; but, if, after careful consideration, they are once formed, they should be honestly expressed.

All facts should be clearly and fairly stated, and great care should be taken not to group nor state them in such a manner as to affect the prisoner. The consequences of such testimony should not, however, prevent a fair and candid statement of the facts.

To all questions put by either side, direct answers will be required, and they should be as short and concise as possible.

As the medical man is simply called to give the testimony for which his knowledge and experience fit him, he should take great care to confine himself to the simple statement of facts and opinions thereon, and not allow his sympathies to be enlisted either for or against the prisoner so as to bias his evidence.

His answers should be made to either the prosecution or the defense in a manner suited to the serious occasion on which he appears, even though he may feel himself provoked or irritated by the course of examination adopted.

A witness should not be flippant or impertinent, nor attempt to argue with counsel. In such cases the witness is generally worsted by the counsel, or rebuked by the Court, and such conduct on the part of a witness only tends to weaken his testimony. What he says under such circumstances is not evidence.

All replies and answers to questions should be made as simple as possible, avoiding technical terms, and should be distinct and audible, and as concise as it is possible to make them.

When it is necessary to make an explanation it should be confined, strictly, to the terms of the question; it should never be ambiguous, undecided, nor evasive. If he has formed an opinion, after careful review of the facts and circumstances of the case, he should give it in plain and

decided language, and be prepared to assign reasons for such opinion; but if he has not formed a conclusion, he is not competent to give evidence, and should allow no consideration to induce him to do so.

A witness may correct counsel on medical subjects when wrong in his views or statements, or may explain medical points, but it is better to confine himself to answering the questions put to him, and to a statement of the facts. Any uncalled-for or unnecessary explanation on the part of the witness may give rise to a charge of bias for or against the prisoner.

Great care should be taken to avoid any appearance of prompting counsel in the conduct of the case.

Partners.

A partnership of professional men differs in some respects from ordinary partnerships; but, in the main, the members of a medical partnership enjoy all the privileges of, and are liable in the same manner as, ordinary partners.

They may hold property, may sue, and be sued, jointly.

These partnerships should be governed by articles of copartnership, carefully drawn, setting forth the duties of the partners and division of the profits; such articles, when executed, are binding, and may be enforced by either partner.

In the absence of evidence to the contrary, the presumption is that the partners are entitled to an equal share of the profits; and where the agreement is only to share the profits, under similar circumstances the losses must be shared in the same proportion, unless restrained from so doing by the copartnership articles. Any partner may contract debts for the firm, bind the firm, receive and receipt for moneys due the firm, pay debts out of the partnership funds, hire and discharge servants, purchase drugs, medicines, etc., on the usual credit, and do anything in relation to the partnership or business.

A partner is not responsible for a free gift made to him exclusively.

Each partner has the right to attend any patient, or to do any business connected with the partnership, unless restrained by the articles.

One partner can not transfer his interests to another, so as to constitute him a member of the partnership, without the consent of the other partner.

The partnership may be dissolved by mutual consent, or by the occurrence of an event made a ground of dissolution by the articles.

A dissolution may be obtained in equity where one partner is systematically excluded from the business, or on the ground of permanent or willful neglect of business, or gross misconduct as to professional or partnership matters by one partner, or on account of the insanity of a partner, or if he has become incapacitated from attending to the business.

A partnership is also dissolved by operation of law, or the death or bankruptcy of a partner, or on his conviction of a felony.

Assistants.

As a general rule, a physician is civilly liable for the wrongful acts of his assistants when they are within the ordinary course of his employment.

Thus, a physician is liable to a civil action for injury done to a patient by the want of proper skill in his assistant; but the injury must have been directly caused by such incompetency.

A physician can not, however, be held *criminally* responsible for the acts of an assistant unless he expressly commands or personally co-operates in them.

In making engagements with assistants, care should be taken to have the remuneration expressly stated; and, if it is to be a portion of the profits, instead of a fixed salary, some memorandum should be made in writing, to avoid any misunderstanding, and to remove the presumption of partnership.

When an assistant is allowed to receive moneys, contract debts in the name of the physician, and perform the ordinary duties of a partner, he will be considered a partner as to third persons, though not between the parties themselves.

Where the assistant is paid by a share of the net profits he is considered a partner as to third persons, but this is not the case if he be paid by a share of the gross earnings.

As between the physician and his assistant, participation in the net profits of a business is evidence of partnership, and requires strong evidence to remove the presumption of partnership of the person so participating.

An assistant may be discharged for willful disobedience of any lawful order; for gross immoral conduct, whether pecuniary or otherwise; for habitual neglect of business; for incompetence or permanent disability from illness, or for any conduct calculated seriously to injure the business of the physician.

Good-Will.

A physician may sell his business to another, and such a sale carries with it what is known in the law as "good-will"; that is, the advantage or benefit which is acquired by an established practice, and by the public patronage and encouragement which it receives by reason of its local position, common celebrity, reputation for skill, or other accidental circumstances.

One may also enter into an agreement with the person to whom such sale is made not to exercise his profession within a certain distance of the place where he formerly practiced, and bonds may be given for the faithful performance of such an agreement; but an agreement by a physician not to practice his profession at all is unlawful, and can not be enforced.

Gifts from Patients.

No person who stands in a relation of special confidence to another, so as to acquire habitual influence over his mind, can accept any gift or benefit from the person who is under the dominion of that influence without danger of having the gift or benefit set aside in a court of equity.

The Courts will not enforce instruments or acts between persons standing in the relation of parent and child, guardian and ward, physician and patient, solicitor and client, and in the various other relations in which one party is so situated as to exercise a controlling influence over the will,

conduct, or interest of the other, where it appears that any undue influence was used in obtaining its execution.

In some cases this influence will be inferred from the nature of the transaction and the exercise of occasional or habitual influence; and where there exists a relation which naturally creates influence over the mind, such as the relation between medical adviser and patient, the Court will infer, from the mere fact of the existence of such relationship between the parties, the probability of the existence of undue influence.

Any agreement between physician and patient, or any gift, bequest, or devise by a patient to his physician, is narrowly scrutinized, and the right of action is not deemed to be established, or proof of the due execution of the instrument, without clear proof outside of the paper of its integrity and entire fairness. The legal presumption is against its validity, and the burden of proving that all was fair, and that the patient acted freely and understandingly, falls upon the physician.

The Courts do not blame or discountenance the influence itself flowing from the relation of physician and patient, unless it has been exerted in the interests of the physician and against those of the patient; and where the influence has been exerted in the interest of the physician it must be *undue*—that is, must amount to coercion, either physical or moral, in order to invalidate the gift.

A person has a right, by reasonable argument or persuasion, to induce another to make a will, and even to make it in his favor; but in the case of a physician and patient it must be clearly shown that the testator thoroughly understood what he was doing, and acted as a free agent.

Whenever a person makes a will in favor of another, or bequeaths him a legacy, the will should not be witnessed by the person in whose favor it is made, as, in order to prove the will and admit it to probate, such person would be compelled to renounce his interest under it before his testimony would be received.

Contracts with Patients.

There is nothing in the relation of physician and patient which precludes them from entering into any contract. There is no reason why a physician should not enter into any ordinary contract, such as the purchase of a horse or a house from any patient, where the relation of physician and patient has no bearing upon it.

The Courts will only interfere to set aside such contracts where they have not proceeded openly and fairly, or when they have actually arisen out of the relation of physician and patient, or where the attendance of the physician, in the case of actual sickness, has continued down to the very time of the contract, and only then when undue influence in obtaining the execution of such contract is proved.

But in these cases the presumption is against the physician, and the burden of proof is upon him to show that there was no unlawful influence exerted.

Recovery of Fees and Charges.

Formerly, in England, the services of a physician, like those of a lawyer, were considered honorary, and no com-

pensation could be enforced, the physician depending entirely upon the gratuity of his patient. Whatever was given was called an *honorarium*. This, however, has long been obsolete, even in England, and the principle of *honorarium* has never found support in American law.

In this State every medical man is entitled to demand and recover in any court of law, with full costs of suit, reasonable charges for professional aid, advice, and visits, and the cost of any medicines or other medical or surgical appliances rendered or supplied by him to his patient. As registration is required, all that is necessary for the purposes of such recovery is that the physician shall have been employed and shall have rendered the services and supplied the medicines or appliances for which he charges; though, if the fact of his being a physician be denied, he will be put to the proof of the same on the trial. This is shown either by the diploma of any incorporated medical college, or by the certificate given by any of the various medical societies previous to 1880. A physician only undertakes to exercise ordinary care and skill, and does not undertake to cure.

He undertakes, however, to practice according to his avowed system and the custom of the particular branch of the profession to which he belongs.

It is no defense, therefore, to an action by a physician for his fees, that no benefit from his care or treatment has been received unless it be shown he has been grossly negligent or has treated the patient unskillfully; nor can the defense that the mode of practice pursued was not agreeable to the views of the patient be interposed successfully, provided the physician adhered to the course of his own system, for the patient is bound by his own selection.

There are no fees prescribed by law, and unless there is a special agreement as to the amount to be charged, each physician is entitled to whatever his services are reasonably worth, and the patient, by the fact of calling in a physician and receiving his professional visits and services, agrees to pay him his usual charges.

These charges may be greater or less, according to the character and standing of the physician employed, but should be reasonable and customary among physicians of corresponding professional standing.

If the charges be objected to, it then becomes a question of fact for the Court or jury whether the services rendered were reasonably worth the amount. This is shown by the ordinary charges of the physician or of the profession for such services, and, in difficult or unusual cases, by the evidence of physicians that the amount charged is not unreasonable. Where a physician has employed an assistant or student in the attendance or treatment of a patient, he may recover whatever the services of the assistant or student are reasonably worth. The patient, however, has the right to object to the visits or treatment of the assistant or student; but, if he receives the visits and treatment without objection, a reasonable compensation may be recovered. When a partnership exists between medical men, and both partners have attended the patient, they should recover in the partnership name. A physician should keep proper books, in which his visits and operations are entered, as these may be

of great service to him, as books of original entry, where the services rendered are disputed. Such books are evidence, and will also be found very useful in making up a bill of the particulars of his claim.

Such a bill is demanded and allowed in almost every case, and should be made out with particularity and correctness.

The customs of the profession are considered as imported into all contracts between medical men and their patients.

In attending servants, a medical man must look to the servant for payment, unless he has an express understanding to the contrary with the master; for a master is not bound to provide medical assistance for a servant, and is only responsible upon an express agreement to pay for such assistance. An infant may contract and render himself liable for medicines and medical aid.

For attendance upon a married woman the husband is always responsible, unless it is understood that the woman intends to bind her separate estate.

If any person, even a mere stranger, direct a physician to attend a poor man, such person is liable for the physician's bill. If, in the absence of the police-surgeon, a physician is called upon by a police officer to visit a sick person in the station-house within the metropolitan district, the physician may recover his fees from the city; but this can only be done when the case is urgent and the regular police-surgeon is absent.

A certificate of attendance should in such cases be obtained, at the time, from the officer on duty.

A physician who reports to an insurance company as to the state of health of a patient can only recover from the company a fee for such services upon an express undertaking to pay such fee, although the report be made upon a form supplied by the company.

A conductor of a railway has no authority to bind the company by a contract entered into with a medical man to attend a passenger injured by an accident on the railway.

The general manager or superintendent of a railway may, however, bind the company by a contract to attend a servant of a railway injured in an accident in the performance of his duties, and they may also, in case of accident, send for medical assistance, and pledge the credit of the company for the same.

It is a general principle, pervading the law of agency, that one who procures services to be done for another is not chargeable as the debtor, unless he omits to make known his principal, or erroneously supposes that he has authority or exceeds his authority, or expressly or impliedly engages to be answerable either by directly promising to pay for them if rendered, or by doing or saying something which justifies the person who is to perform them in supposing that the one who applies to him engages to pay for them.

In rendering bills for professional services, great care should be taken to make the bill out in the name of the person who has ordered the services, so that no question may arise as to whom credit was given.

As a profession, we are happy to appreciate that the State, in passing the law of 1880, has reduced the number of

bodies competent to legalize practitioners of medicine from one hundred and fifty to eleven. These eleven bodies are the *medical colleges* of the State. All candidates for qualifications to practice medicine must produce a certificate of three years' pupilage; but there is no established standard of knowledge required for the degree of Doctor of Medicine.

The scope of the examinations for a degree is left entirely to the discretion of the faculty of the eleven medical colleges. For the foregoing reasons some of the most thoughtful of our profession have set on foot a plan to enact a law whereby we shall have a state board of examiners in medicine. The Erie County Society is soliciting the co-operation of other medical societies to aid it, in carrying forward this plan, to get their proposed bill before the Legislature.

The argument I should advance in favor of some more definite knowledge regarding the qualifications of one who has received a degree in medicine is exemplified in the United States Army Medical Board. No matter how many literary or medical degrees one may have received, nor from what source they came, the United States will not appoint a surgeon to go on to the frontier and minister to her sick soldiers until the Army Medical Board have attested his qualifications. Neither will a man be appointed on the staff of one of our own charity hospitals without first showing before a medical examining board that he is qualified.

If the United States demand and require such examination in the interest of her soldiers, and the State requires the same for the protection of her paupers, why should she not require it for the protection of her taxable citizens?

NOTE.—The abstracts of laws given in this paper were for the most part furnished by Mr. R. Duncan Harris, of the New York bar.

THE NECESSITY OF PRIMARY PERINEORRHAPHY.*

By CHARLES R. CRANDALL, M. D.,
PORTLAND, ME.

THE subject to which I invite your attention to-night is not new, but rather one of vast importance. I disclaim, at the outset, all pretension toward originality, and offer, as my warrant for reviewing what has been discussed so many times before, the necessity of creating a professional sentiment favorable to primary perineorrhaphy. I feel that this simple but necessary procedure should become established as one of the imperative duties of the obstetrician, to the end that human suffering may be averted and human lives prolonged.

Preliminary to the remarks I shall make, I desire to report three cases, occurring in my own practice, which illustrate the utility of the primary operation.

CASE I.—R. S., Germain, aged eighteen, a primipara, of large stature and in perfect health. She was well during gestation, and was confined at full term. Not being summoned in time, when I arrived I found that labor had terminated. The nurse informed me that the child was born head first, that she had cut

* Read before the Cumberland County Medical Society, December 26, 1883.

the cord, and that the placenta was still undelivered. Proceeding at once to remove the placenta, I observed that the perineum was lacerated through to the anal sphincter. As soon as the patient was in a proper condition I proceeded to perform the primary operation. This done, she was put in position, her legs were bandaged, and opium was given, with a view of relieving pain and confining her bowels. All went well until the third day, when she had an attack of diarrhoea, and, during some of her operations, passed four large ascariæ lumbricoides. When I was informed regarding what had taken place, I concluded that there had been sufficient irritation and straining to render my primary operation a failure. To my surprise, however, when I removed the sutures on the seventh day, I found perfect union, and she got up at the end of two weeks in a good condition.

CASE II.—Mrs. J., an American, aged twenty-three, and a primipara; gestation normal. When called to attend her in labor I found her vulva, vagina, and pelvis in a normal condition, and the os uteri slightly dilated. I was enabled, during the first examination, to diagnose a head presentation with the occiput in the left anterior position. Her labor went on satisfactorily for about ten hours, when there ensued a failure of general strength accompanied by uterine inertia. At this time the head was well down upon the floor of the pelvis, but had ceased to make visible progress. Everything seeming normal, I gave her stimulants, with the belief that she would be enabled to deliver herself in a little while. But it became evident that no progress was being made, so I administered ether, applied the forceps, and made moderate traction. The head descended readily, and the occiput rotated toward the pubic arch. As the vertex entered the vulva I removed the forceps, with a view of saving the perineum, and, after one or two pains, the head was born without injury to that structure. Almost immediately a strong pain followed, forcing the fœtus through the vulva rapidly. I soon saw that the perineum was ruptured, the anal sphincter destroyed, and the recto-vaginal septum torn to the extent of an inch and a half. This calamity was plainly due to the rapid delivery and the unusual development of the fetal shoulders. The infant weighed ten pounds and some ounces. Having decided upon performing the primary operation, I sent for a professional friend to assist me. Having cleansed the parts, they were brought into perfect apposition and secured with six silk sutures. The patient was then placed in the prone position and her legs bandaged together. The nurse was directed to give her morphine sufficient to relieve pain, catheterize her bladder twice daily, and administer a warm carbolized vaginal douche every six hours. Her diet was to consist of a moderate quantity of liquids, and she was to use the bed-pan after the third day. No bad symptoms ensued. I removed the sutures on the seventh day and found perfect union. She steadily convalesced, rising from her bed on the fourteenth day "feeling as well as ever."

CASE III.—Mrs. A., an American, of very slight stature, aged twenty-five, and a primipara. Her gestation was normal, but it was noticeable, from first to last, that her form was remarkably small. Indeed, as late as the eighth and ninth months she was able to wear her ordinary garments without being obliged to lengthen her waistbands. As her sister said, "She never saw any one so small and carry their child so low down." She had been in labor several hours when I saw her, and had made some progress. Upon making examination, I found the vulva, vagina, and pelvic diameters apparently normal. The os uteri was slightly dilated, and the fetal head was presenting with the occiput in the left anterior position. After several hours the head became engaged in the superior strait, but did not descend satisfactorily. During the early stage of her labor I found that there was a most limited quantity of amniotic fluid, and

it was owing to that fact that she had been so very small during her pregnancy. While manipulating the fetal head I ruptured the membranes, but not more than two or three ounces of amniotic fluid escaped. The head still remaining at the brim of the pelvis and, no advance being made, I decided to etherize and apply the forceps. Not being well assisted, I sent for two physicians. Soon after their arrival we applied the forceps with much difficulty, and each in turn made traction, but to no avail. Having the forceps in hand, I allowed the head to recede, made readjustment, and accomplished the delivery. The fœtus weighed eight pounds and a half, and had a large and peculiar-shaped head. The bi-parietal diameter was abnormal, and the parietal protuberance, which had presented anteriorly, had so pressed against the symphysis and rami of the pubes that it was markedly indented and had caused the delay. Owing to the size of the head and the prolonged use of the instrument, the maternal tissues were injured and the perineum was ruptured down to the sphincter ani. I will not enter into the after-history of this case, but simply say that I proceeded at once to perform the primary operation, using four silk sutures. On the sixth day I removed the sutures and found a perfect union and a good perineum.

As yet I have not become a convert to the new and skeptical view that "no such body exists as the perineal body," so I shall base my remarks upon the old "orthodox doctrine" that there is such an anatomical structure. I believe that there is a "body," or "structure," situated between the lower portion of the vagina and rectum, composed of fascia, adipose tissue, areolar tissue, muscular tissue, blood-vessels, and nerves, and that it is very properly known as the perineal body. Having recalled the structure we are to discuss, let us consider for a moment its important functions, and in presenting these I shall quote the words of that matchless instructor, Dr. T. G. Thomas:

1. "It sustains the anterior wall of the rectum, thus sustaining the equilibrium between the rectum, vagina, cervix, and body of uterus.
2. "It sustains the posterior wall of the vagina.
3. "Upon the posterior vaginal wall rests the anterior, upon that the bladder, and against the bladder the uterus—all of which, to a great degree, depend for support upon the perineal body.
4. "It preserves the proper line of projection of the contents of the bladder and rectum, and thus prevents the occurrence of *tumours*, which is a frequent cause of pelvic displacements."

From this brief statement of the function of the perineal body we comprehend without argument its great importance in the physical economy of woman. Now let me review, in a concise manner, the unfortunate conditions which at times occasion rupture of the perineum.

1. A too rapid labor. In primiparous women, when the expulsive contractions are frequent and powerful, the perineum may be ruptured before it has time to dilate.
2. Want of elasticity. In patients in whom the tissues are rigid, or excessively fat or fleshy, there is danger of rupture because sufficient dilatation can not take place.
3. Straightness of the sacrum. In patients in whom there is an imperfection or absence of the normal sacral curvature, the fetal head is driven down directly upon the perineum, and generally causes rupture.

4. Narrowness of the vulvar orifice. As is well known, females vary greatly in this respect, and in those having a small orifice there is a natural predisposition to rupture during the first labor.

5. Abnormal presentations. In vertex presentations followed by occipito-posterior positions, the longest diameter of the head distends the perineum. The mechanism of this form of labor, showing how the head advances in the occipito-posterior positions, is beautifully shown by Lusk in his "Science and Art of Midwifery," p. 178. There it will be seen that, when the occiput rotates backward into the hollow of the sacrum, pressure upon the perineum is inevitable, and will probably cause rupture.

6. Abnormal diameters of the fetal head and shoulders. Some authorities affirm that rupture is almost always caused by the head, while others assign it more frequently to the shoulders. In two instances I have seen ruptures which were plainly due to excessive "bis-acromial diameters," and I look upon a carefully regulated delivery of the shoulders as being of as much importance as management of the head.

7. Instrumental delivery. I have heard it said that more perineums were destroyed by the forceps than by all other causes. Baudelocque declared "the forceps has been more injurious than useful to society."

Undoubtedly, instruments in tired, nervous, and unskilled hands have caused inestimable damage. Many instruments are faulty in construction, oftentimes they are not removed soon enough, and frequently traction is made in the wrong direction. Hence the value of the rule to use a forceps as seldom as possible, to do so with great care, and to take it off as soon as the fetal vertex enters the vulva.

The foregoing are the principal causes which produce the unfortunate accident, and they should be understood by every physician, so that he may do his duty in endeavoring to avoid its occurrence. Valuable as it is to be able to perform primary perineorrhaphy, it is highly more important to guard against the causes and prevent the necessity for the operation.

At the present time perineal rupture is divided into two principal varieties—partial and complete—and these again are subdivided into four, to be defined hereafter. These subdivisions and varieties are largely imaginary and arbitrary, for practically there are as many as there are women who undergo this form of rupture. No two cases are exactly alike, yet there are general appearances and general rules bearing thereon which are of quite universal application.

The four subdivisions alluded to have been generally adopted by the profession, and are as follows:

1. "Rupture of the fourchette and perineum";
2. "Rupture to the sphincter ani";
3. "Rupture through the sphincter ani";
4. "Rupture through the sphincter ani involving the recto-vaginal septum." (Thomas.)

As a rule, the first degree of rupture shows but little externally after the parts have contracted, but it should ever suggest a thorough vaginal examination, for at times the integumentary rupture is slight, while the vaginal and perineal is extensive, demanding the introduction of sutures. The second degree necessarily involves the sphincter vaginae, and

is too serious an accident to be trusted to spontaneous cure, for it is frequently followed by immediate and secondary evils. The third and fourth degrees, known as complete rupture of the perineum, are among the most serious accidents attending parturition. They are accidents that should command immediate attention, as much as or more than a fracture or dislocation. In exceptional cases the patient may rally, and experience but little suffering, but the rule is that, if neglected, she will never see another well day, and will become an object of pity and misery.

Solution of continuity in the genital tract of the parturient primipara is very common. I am among those who believe that a rupture of the fourchette, and more or less of the perineum, occurs in almost every primipara, whether instruments are used or not, and that the event is practically unavoidable. It has occurred in all the primipara I ever saw, and we are assured by the best authorities that it invariably does occur. Playfair says: "In almost all first labors the fourchette is torn." And Lusk adds: "Owing to the small size of the vaginal orifice, tears through the mucous membrane and erosions of the vulva, and, in the primipara, the rupture of the frænulum, are to be accounted for as the almost inevitable consequence of childbirth."

The more extensive forms of laceration of the perineum, I believe, occur, to a greater or less degree, in the majority of primiparous women, and this regardless of all the precautions that may be taken. At the obstetric clinic at Halle, Olshausen professes to have reduced perineal injuries in the primipara to about 21 per cent. by precautionary measures, but I venture to assert that no such average can be found in private practice. Take it in America, where the tendency is toward a decline in the development of the bony and muscular structure of mothers, while on the contrary there is a tendency toward an increase in the diameters of the fetal head, and it is my opinion that these statistics can not be confirmed. Three cases in my own practice illustrate how easy and almost unavoidable it is for such accidents to occur. In the first case it was due to natural conditions, for the fœtus was born in the absence of any attendant; the second was plainly due to the small size of the mother and unusual size of the fœtus; while the third was due to the limited bony structure of the mother and marked increase in the diameters of the fetal head.

To lay down absolute rules by which the majority of perineal ruptures may be avoided is, of course, impossible, yet nearly every physician who has considerable obstetric experience makes the attempt. Hence Olshausen says: "Support the presenting part instead of the perineum and regulate its progress." Ritgen's method "consists in lifting the head upward and forward through the vulva, between the pains, by pressure made with the tips of the fingers upon the perineum behind the anus, close to the extremity of the coccyx." Goodell recommends "hooking two fingers into the anus and drawing the perineum forward during a pain, to remove the strain from the thinned border of the vulva and to promote elasticity of the tissues." Lusk suggests: "Between pains I have been in the habit, in case of rigidity, of alternately drawing the chin downward through the rectum until the head distends the perineum, and then

allowing it to recede." Lastly, Parker urges the highly sensible and practical view of the great value of anæsthetics as another important means of preventing the accident. He says "they are indicated, for this purpose, in four classes of cases"; but, for brevity, I cite only three:

1. "In that form of rigidity of the perinæum depending upon excessive irritability of the muscular fibers that enter into its composition.

2. "In those cases where the danger arises from the violent and rapid uterine contractions, driving the head or the shoulders through the vulva before the perinæum has been sufficiently expanded.

3. "Long-continued pressure of the head may produce congestion and inflammation of the perinæum, which not only render it more unyielding, but more easily torn. It becomes hot and dry and very painful, and uterine action becomes irregular and feeble in consequence of this condition. Now, under these circumstances, I have seen the inhalation of chloroform followed by immediate relaxation of the perinæum and a restoration of the normal moisture and temperature of the parts, while efficient action of the uterus was at once resumed."

But, despite all the foregoing good suggestions, partial and complete ruptures will occur, and it is for the attending physician to know what to do, and have the disposition to pursue the right method, to secure the best results for his unfortunate patient.

(To be concluded.)

Book Notices.

BOOKS AND PAMPHLETS RECEIVED.

Elements of Physiology. By Henry Power, M. B. Lond. F. R. C. S., Ophthalmic Surgeon to St. Bartholomew's Hospital, London, etc. Illustrated with 47 Engravings. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. x-389.

The Field of Disease: a Book of Preventive Medicine. By Benjamin Ward Richardson, M. D., LL. D., F. R. S., etc. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. 737.

On the Wasting Diseases of Children. By Eustace Smith, M. D. Lond., Fellow of the Royal College of Physicians, etc. Fourth Edition. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. xxiv-372. [Price, \$3.]

Opera Minora: a collection of Essays, Articles, Lectures, and Addresses, from 1866 to 1882, inclusive. By Edward C. Seguin, M. D., Clinical Professor of Diseases of the Mind and Nervous System in the College of Physicians and Surgeons, New York, etc. New York: G. P. Putnam's Sons, 1884. Pp. x-687. [Price, \$4.50.]

Transactions of the American Surgical Association. Volume the First. Edited by J. Ewing Mears, M. D., Recorder of the Association. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. xxxi-568.

LETTER FROM ST. LOUIS.

The College of Physicians.—A Training-School for Nurses.—The Society of the Red Cross.—A Water Famine.—The Mysterious Death of a Family.—The "Weekly Medical Review."—The Medico-Chirurgical Society.—Contagious and Infectious Diseases.

ST. LOUIS, January 18, 1884.

To the Editor of the New York Medical Journal:

THE St. Louis College of Physicians and Surgeons is at the present time passing through a season of trial and tribulation. As stated by the "Globe-Democrat" of Wednesday, it "presents the curious spectacle of an institution the large majority of the faculty of which have resigned and yet continue their lectures, and of a student force who have left in a body and yet attend the lectures."

The *casus belli* is as follows, so far as the facts can now be presented: A well-known surgeon organized the college some four years ago, and there has been a good deal of the "one-man power" in the management of the institution. The surgeon in question secured the incorporation of a board of trustees of his own selection; he engaged the several members of the faculty, and his hand was felt in every act of the trustees or faculty.

Until quite recently there seemed to be no questioning as to the expediency or right of that state of things. Now and then changes were made in the organization of the faculty. Certain names were dropped and others were added.

Last autumn some members of the faculty felt that there was altogether too much of an autocracy in the management of that institution to be consistent with the principles of the government under which we live. They felt that the other members of the faculty should have some rights and privileges. Accordingly, they made a demand that the faculty as a whole should elect the dean and other officers of the faculty (the trustees had appointed the surgeon alluded to dean of the faculty), and that they should have a voice in the removal and appointment of members of the faculty. They demanded also the right to know the financial status of the institution, and that they should have certain rights and privileges with reference to

the stock of the institution, which it is stated carries a debt of about \$7,000.

A formal petition to the Board of Trustees for a reorganization was presented a few weeks ago. As a counter-move, the organizer of the college secured the adoption by the Board of Trustees of a set of by-laws confirming him in all the powers which he had been exercising. A resolution was also adopted requiring all the members of the faculty to sign these by-laws, which were read to the faculty at their regular meeting. Some said at once that they would not sign the paper; others chose to take time for consideration. After a few days, during which they were informed that they must sign the paper soon or resign their chairs, or be discharged, they determined to resign. In accordance with this conclusion, a formal resignation was prepared and signed by all the members of the faculty except three. This was sent to the president of the Board of Trustees. In the mean time disaffection spread among the students. They were told, however, that there was no trouble to be apprehended; that the institution was on a firmer foundation than ever before. On the other hand, a statement of the affair was made to the class by members of the faculty. The students expressed their sympathy with the faculty and their decided disapprobation of the course of its ruling member. They threatened, more or less definitely, that they would summarily eject any professors who might be substituted for the present corps. They held meetings, and formally resolved that, if the faculty left, they too would withdraw in a body.

Then the surgeon began to "crawfish," maintaining that he did not wish to have the faculty resign; that, in fact, he would like to have everything go on smoothly, as it had done. In short, all that he wanted was "to be let alone."

The resignations were not accepted, and, further than that, the professors have continued to deliver their lectures regularly, acting under the conviction that they were under obligations to the class in attendance not to discontinue their lectures in the middle of the term.

Considerable interest is felt by the profession through the city as to the outcome of the squabble. It has been a matter of surprise to some that the faculty have held together as long as they have, and many are doubtful of the reorganization of the institution.

A training-school for nurses has been organized here on a basis similar in many respects to those in Boston, New York, and other eastern cities. A building for the Nurses' Home has been secured and furnished just across the street from the City Hospital. Arrangements have been completed for some eighty lectures to the nurses by a number of prominent physicians, while the details of practical work will be learned by actual service in the hospital. The course will extend through two years, and diplomas will be given to those who successfully complete the course of study and service. The ladies who are interested in this training-school are among the most prominent society ladies in the city, and the success of the institution is guaranteed by the character and influence of those who are urging it on. It is intended to limit the number of the nurses during the first year to seven, and the work will be begun early in February. A meeting of the lady managers was held at "the Home" on Tuesday, January 15th, to inspect the house and its furnishing, and there was a general feeling of satisfaction with the arrangements thus far perfected.

The Red Cross Association here is working now to procure a hospital car, to be supplied with cots and all necessary remedies and appliances for use in case of railway accidents.

During the intensely cold weather in the early part of last month there were two very disastrous fires here, and the waste of water, caused by people allowing their hydrants to run in

order to prevent them from freezing, together with the drain made by the Fire Department, caused a complete exhaustion of the high-service reservoir, and a consequent water famine at the Female Hospital, Insane Asylum, and Poor House. This necessitated hauling water with teams for three days at an expense to the city of nearly six hundred dollars.

Within five weeks a family of five persons, in the western part of the city, have died, one member after another being attacked with symptoms which rapidly grew worse and terminated fatally in a few hours. The first victim was an eight-months-old baby, who was taken with purging and vomiting, and died within a few hours. In returning from the funeral, the mother complained of feeling unwell. She grew rapidly worse, and died five days afterward. The cause assigned for her death was bilious fever. A few days later the oldest child, a boy of five years, was seized with similar symptoms and died; then the remaining child also died in the same way—congestion of the bowels being given as the cause of death in the physician's certificates. Now the father has just died with the same symptoms, having been ill two days; and the sister, who assisted in nursing the sick ones, is also quite ill. No cause has been discovered as yet for this remarkable fatality. The premises have been carefully examined, and there seems to be no evidence of local cause for the disease; nor have any evidences of poison been discovered.

I am informed that Dr. D. C. Gamble, who has been for a year past the St. Louis editor of the "Weekly Medical Review," has resigned, and will be succeeded by Dr. Julius Wise, whose name is familiar to those who have followed the course of medical journalism in the West during the last few years, as the first editor of the "Mississippi Valley Medical Monthly."

The St. Louis Medico-Chirurgical Society, at a recent meeting, adopted a number of amendments to the constitution and by-laws. This society has never before had a committee on ethics. By one of the amendments the Executive Committee is made the Committee on Ethics. It is to be hoped that this society will not become the scene of such rancorous discussion on questions of medical ethics as has been the case in the St. Louis Medical Society.

The Health Commissioner issued circulars, not long since, to all the physicians in the city, calling their attention to the ordinance requiring them to report to the Board of Health all cases of contagious and infectious disease, and notifying them of the penalty for neglecting to comply with the ordinance.

Proceedings have been instituted against several prominent physicians who have been negligent in this regard, and it is believed that more prompt observance of the ordinance will be the result.

PHYSIOLOGY AND HYGIENE IN THE PUBLIC SCHOOLS.—An absurd bill has been introduced into the Legislature of the State of New York, making a knowledge of these branches incumbent upon teachers in the public schools. When we consider how much of a subject a teacher ought to know in order to teach a little, it becomes evident that a corps of teachers competent to give instruction of this sort at all worthy of the name is utterly unattainable without a very large increase in the appropriations for school purposes. The bill is understood to have emanated from a temperance society, its prime object being to have the physical evils of dram-drinking impressed upon the minds of the young. However worthy the motive may be, the method adopted is not one that the State ought to enforce.

A NURSE'S MISTAKE lately caused the death of a patient in the lunatic asylum at Norristown, Pa. Carbolic acid was administered instead of the medicine ordered for the patient, although both bottles were labeled distinctly. The interpretation put upon the occurrence is that the nurse's mind was distracted by anxiety concerning a sick relative.

NEW YORK, SATURDAY, FEB. 2, 1884.

THE COMING MEETING AT ALBANY.

THERE is reason to believe that the seventy-eighth annual meeting of the Medical Society of the State of New York, to be held in Albany on Tuesday, Wednesday, and Thursday of next week, will prove exceptionally profitable. In addition to the programme we have already published, several papers of interest have been promised. The complaint has often been made, either that the city men contributed little or nothing to the programme, or, on the other hand, that the New York specialists took up the greater part of the time, to the exclusion of the general practitioner, and especially of the country practitioner. It is not easy to see how the most determined of grumblers can apply either of these criticisms with any semblance of justification to the list that has been made up for this year's meeting. Indeed, a more even balance between the metropolitan and the rural elements could scarcely be imagined; and the same may be said of the ratio of the specialists to the general practitioners. It will be an evil day for the society when either of these elements of the profession in the State holds itself back out of pique, and it is satisfactory to find, as can safely be inferred from the list in question, that there is no present danger of such an attitude being assumed by either.

The scientific matter provided is ample for the most profitable employment of all the time at the disposal of the meeting, but there is little ground for the hope that a portion of the time will not be squandered in further action on the code of ethics. Unfortunately, the element of time so wasted will probably be small in proportion to the amount of intellectual activity thus diverted from what would ordinarily be the only legitimate channel. However, the ethical dispute must be settled one way or another. It is to be hoped that quick work will be made of it, and that votes rather than speeches will be recognized at the outset as the one thing in order. All the delegates and all the permanent members understand the questions at issue thoroughly, and it will be time absolutely thrown away to attempt to make converts by argument. It is desirable that the meeting should be a full one, in order to a decisive settlement; and there is little room for doubt that it will be. We look to see both parties gathered in force. Notwithstanding the recent organization of the New York County Medical Association, and the avowed purpose of the old-code party to form like societies in the other counties, and ultimately a new State society, it is inconceivable that that party would not vastly prefer to rule the old organization, with its unquestioned legitimacy, its prestige, and its legal status, rather than to pin its hopes of supremacy to the venture of a rival body made up of representatives from counties many of which can scarcely keep up

one society with any considerable approach to credit. This much may be said on general principles; in addition, we may point to the urgent appeals that have been published in the organs of the party. Reasoning from such considerations as these, the new-code party, for its part, will see the necessity of being on hand in full strength, in spite of its recent telling victories in this city.

The question as to the result of the contest ought not to be very difficult to answer. If the opponents of the old code do not suffer themselves to be deluded into a false sense of security, the action taken last year can not be reversed. A canvass of the State, undertaken by the old-code party, has, indeed, been widely proclaimed as showing that a preponderating proportion of the profession is in favor of the restoration of the old code; but it should be remembered that quite the same forecast was made, and on grounds apparently identical, in regard to the election in the New York County society, but proved fallacious. There is a large party in favor of abolishing all codes—the no-code party—but its members can probably all be counted upon to vote in favor of sustaining the new code under the present circumstances, for they feel that they are under fire, and, having taken a hand in the fight, they will not change their tactics in the presence of the opposing forces. It seems exceedingly probable, therefore, that the new code will be reaffirmed, and very likely by a majority greater than that of last year.

THE PROPOSED STATE EXAMINING BOARD.

THAT the dignity and interest of the profession in the State of New York demand a definite and uniform test for admission to its ranks there can be no doubt, and there is reason to believe that there is not much dissent from the opinion that the most practicable and equitable plan for applying such a test involves the creation of a State board of examiners. As to the precise constitution of such a board, and as to just how much power should be delegated to it, there is considerable diversity of opinion among earnest and thoughtful men. The problem is a novel one, and it would not be strange if the first attempts at its solution should fall far short of the mark.

The question ought to secure a good deal of attention from the State society next week, but whether the meeting will be properly prepared to take final action, in the form of a positive recommendation to the Legislature, is a matter of uncertainty. It seems to us to be desirable that no decided action in this direction should be taken until the better elements of the profession are practically agreed upon the leading details of the plan. We think it was wise, therefore, on the part of the Medical Society of the County of New York to take the course it took last Monday evening, when it declined to give its assent to a particular bill, but contented itself with a general declaration in favor of a State board.

The chief difficulties will be to harmonize the interests of the profession as a whole with the just claims of corporate interests, and to make the result of this adjustment acceptable to the people of the State. It is not to be imagined that a bill can be devised which shall quite embody the preferences of every

element in the profession, but the closest possible approach to such a desideratum ought to be made before the representative body of the profession in the State goes before the Legislature with a bill. Doubtless several bills will come up for consideration at Albany next week, and, so far as the attention of the meeting has to be diverted from scientific work, it can not employ its time to better advantage than in scrutinizing the drift of these various bills. Some may be offered that, far from promoting the real purposes of the movement, will secretly aim at thwarting it. Indeed, we have seen the draft of a bill that can not be interpreted otherwise—to the careless reader it would seem to promise no end of reform, but in reality it leaves things practically as they are now. It simply throws a sop to Cerberus. Its object is veiled with so flimsy a disguise that its promoters are quite likely to shrink from bringing it before the meeting, or seeking to get its indorsement by the profession in any other manner, but the meeting will fall short of its duty if it fails to drag it forth and expose its rottenness. There will be men present at the meeting who know precisely what we allude to, and they know, too, what the effect will be if the bill in question is allowed to go to the Legislature without having been unmistakably condemned by the profession. There is a suspicion, indeed, that its defeat is the real aim of its promoters, who would then spread the impression broadcast that no measure looking to the establishment of a State board could be got through the Legislature.

LARGE DOSES OF QUININE.

We would direct the attention of our readers to three articles in this issue of the journal, by Professor Smith, Professor Wright, and Dr. Winters, on the untoward effects that may sometimes follow the use of large doses of the cinchona alkaloids, taking quinine as the representative of the class. This agent has figured so largely in our therapeutics of late years, and has been found to be of such wide applicability in the treatment of disease, that there have been indications that it was likely to meet with that popular repugnance which the last generation bestowed upon calomel—a repugnance that seems to be born of the feeling that a drug so potent for good must necessarily have equal powers for harm. These popular antipathies are apt to rest on a groundwork of fact, but nevertheless their constant obtrusion in the physician's daily intercourse with patients undoubtedly cripples his freedom of action in the delicate field of therapeutics, and therefore his efficiency in combating disease. It is most unfortunate for any medicinal agent to be made the subject of such a prejudice.

Nothing could be more certain than that the three gentlemen to whose articles we allude view the matter in precisely this light. Indeed, Dr. Smith expressly deprecates any inference from his paper favoring a prejudice of this sort. At the same time, each of these gentlemen undoubtedly feels, as it is difficult to see how any one can avoid feeling, that the surest way to forestall an unreasoning clamor against a drug is to state candidly and faithfully the dangers that occasionally attend its use. There is another reason why, it seems to us, the writers

of the articles in question should be held to have done well in bringing their observations before the profession, and that is that, by pointing out what may be called the contra-indications to the cinchona alkaloids, they enable the profession to continue to use those drugs with a discrimination and a consequent safety that would otherwise have been lacking. We as a profession are not answerable for the imperfections of the agencies we use, but we should be culpable indeed if we failed to discover those imperfections, so far as possible, or to diffuse the necessary cautions to be drawn from a knowledge of them.

MINOR PARAGRAPHS.

A CAUTION TO SUBSCRIBERS.

It has come to our knowledge that a swindler is going about the country soliciting subscriptions for various medical journals, including the "New York Medical Journal." He takes care to collect the money, but those who give it to him do not receive the journal. The individual in question is, or pretends to be, a deaf-mute. So far as our information goes, the last scene of his nefarious operations is Dayton, Ohio, where he gave a victim a receipt signed "W. R. Taggart, for C. B. Slewin, of Fort Wayne." Those who wish to subscribe for this journal are informed that the person alluded to has no authority to solicit subscriptions for it, and that we know nothing about him except what has been written to us by his victims.

THE "ANNALS OF ANATOMY AND SURGERY."

We regret to have to record the suspension of this excellent journal. During the few years of its existence it has filled a place altogether unique in medical literature in this country, and perhaps one that is not filled in any other country, if we take into account the admirable historical essays contributed by Dr. Fisher, of Sing Sing. They dealt with the fathers of medicine, those old-time worthies about whom most of us know very little, but whose lives and whose writings it would be profitable for us to make ourselves acquainted with. The reason of the suspension is stated to be the departure of the editors for Europe. In their circular announcing the fact they hint that the publication may be resumed at the beginning of next year, and we trust that such may be the case.

A STEAMSHIP COMPANY'S STINGINESS.

On several occasions we have alluded to the unworthy treatment which steamship companies show now and then toward their medical officers. The latest and most flagrant instance that has come to our knowledge is that of the Red Star Line, sailing between Philadelphia and Antwerp, which compels the surgeons of its vessels to mess with the petty officers and second-class passengers. The opinion has been expressed that the medical officers of the line really have the matter in their own hands, and that they should not submit to such treatment. It seems to us, however, that they ought not to be left to cope alone with a powerful corporation, but that the profession at large should feel itself insulted through them, and should use its influence in every legitimate way to make the company feel that it has been too high-handed.

A SCARCITY OF ANATOMICAL MATERIAL IN CHICAGO.

The "Weekly Medical Review" states that there has been a decided scarcity of anatomical material in Chicago during the present winter, and that, in consequence, resort has been had to

the desecration of graves. According to the journal quoted, the deficiency seems to have been due to a defect in the law, which is simply permissive but not mandatory upon the county officials. So long as they were paid for their trouble in handling the bodies (at rather exorbitant rates, it appears) there was no trouble, but the colleges demurred, and then it was found that they could not compel the delivery of subjects.

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 22, 1884:

DISEASES.	Week ending Jan. 22.		Week ending Jan. 29.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	3	0	1	1
Typhoid Fever	7	3	8	2
Scarlet Fever	67	9	90	11
Cerebro-spinal meningitis	5	5	6	4
Measles	40	4	52	14
Diphtheria	36	16	59	20
Small-pox	0	0	1	0

SMALL-POX.—An Italian sailor was admitted to the Long Island College Hospital, in Brooklyn, on the 9th of January, and it is reported that three cases have since occurred in the institution as the result. All the patients were promptly removed to the Small-pox Hospital. The Illinois State Board of Health has called attention to the prevalence of the disease in Prague, through which city, it says, Bohemian emigrants leaving for America must pass on their way, the destination of most of them being Chicago and the Northwest.

THE ADJOURNED DISCUSSION ON PUERPERAL FEVER, being the discussion of Dr. T. Gaillard Thomas's paper entitled "The Prevention and Treatment of Puerperal Fever," published in our issue for December 15th, will be opened at the next meeting of the Academy of Medicine, to be held Thursday evening, February 7th, by the president of the Academy, Dr. Fordyce Barker, who will read a paper on the subject.

A RECEPTION TO PROFESSOR PARVIN.—The Alumni Association of the Jefferson Medical College, of Philadelphia, gave a reception in honor of Professor Theophilus Parvin, M. D., LL. D., at the St. George Hotel last Monday evening. The affair is described as having shown the well-known enthusiasm of the Jefferson men as it has seldom been shown before; and certainly such a display may well have been called forth by the accession of so strong a man to the faculty of their alma mater, and of so genial a gentleman to the Philadelphia profession.

THE MEETING OF THE STATE SOCIETY.—The secretary of the New York delegation informs us that he has made arrangements by which members, delegates, and other physicians in the city who intend to be present at the meeting can get return tickets to Albany for five dollars. Application should be made to Dr. Charles L. Dana, 66 West Forty-sixth Street. Dr. Dana feels quite sure that like arrangements can be made with the railways by physicians in other parts of the State.

The Hudson River Railroad trains from New York to Albany run as follows:

Leave New York.	Reach Albany.
8.40 A. M.	12.10 P. M.
10.30 "	2.40 "
3.30 P. M.	7.45 "
6.00 "	10.15 "

Most of the New York delegation will take the 3.30 P. M.

train on Monday, parlor-car accommodations having been secured.

THE HEALTH OF ATLANTIC CITY.—A report having been spread some weeks ago that scarlet fever was prevailing extensively at Atlantic City, the Board of Health of the town announces that there is not a single case within its limits.

A BUREAU OF ANIMAL INDUSTRY.—Under this title a board is proposed in a bill lately introduced into Congress, the functions of which shall be to prevent the exportation of diseased meat, and to provide for the extermination of the infectious diseases of cattle.

CREMATION IN BOSTON.—A cremation society has been organized in Boston, and it is said that authority will soon be asked for to establish a crematory in the vicinity.

THE LATE DR. J. MARION SIMS.—It is announced that a former patient of Dr. Sims's will give a bronze bust of the deceased surgeon, to be deposited in the new building occupied by the Harvard Medical School.

THE HUDSON RIVER STATE HOSPITAL FOR THE INSANE.—A bill has been introduced into the Senate appropriating \$45,000 for an addition to the institution. An Assembly bill appropriates the sum of \$45,000 to cover the cost of providing accommodations for fifteen hundred additional patients.

THE YALE COLLEGE BUILDINGS are pronounced to be in good sanitary condition by a committee consisting of Professor Chandler, of New York, and Professor Brewer and Dr. Lindsley, of the New Haven Board of Health.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.—We learn that Dr. Ambrose L. Ranney has been appointed professor of applied anatomy.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending January 26, 1884:*

WHITING, ROBERT, Passed Assistant Surgeon, detached from the Hospital at Norfolk, Va., and ordered to the U. S. S. Colorado.

FITTS, H. B., Assistant Surgeon, detached from the U. S. S. Jamestown, and ordered to the Coast Survey Steamer Gedney.

ANDERSON, F., Passed Assistant Surgeon, granted leave of absence for six months.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, February 4th:* New York Academy of Sciences (Section in Biology); Medico-Chirurgical Society of German Physicians; Brooklyn Anatomical and Surgical Society (private); Utica (N. Y.) Medical Library Association.

Tuesday, February 5th: Medical Society of the State of New York (Albany—first day); New York Obstetrical Society (private); New York Neurological Society; Elmira (N. Y.) Academy of Medicine; Buffalo Medical Association; Ogdensburg (N. Y.) Medical Association.

Wednesday, February 6th: Medical Society of the State of New York (second day); Medical Society of the County of Richmond, N. Y.; New York Medico-Legal Society.

Thursday, February 7th: Medical Society of the State of New York (third day); New York Academy of Medicine (Adjourned Discussion on Puerperal Fever); Society of Physicians of the Village of Canandaigua, N. Y.; Medical Society of the County of Ocean, N. J. (Tom's River).

Friday, February 8th: Yorkville Medical Association (private).

Saturday, February 9th: New York Medical and Surgical Society (private).

Proceedings of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of January 28, 1884.

S. O. VAN DER POEL, M. D., President, in the chair.

THE DELEGATION TO THE STATE SOCIETY.—The By-Laws were suspended for the purpose of proceeding at once to the transaction of certain new business, and the secretary read the resignations of Dr. J. H. Ripley and Dr. Samuel Sexton as delegates, which, on motion, were accepted. Dr. F. R. Sturgis then nominated Dr. W. Gill Wylie to fill the vacancy created by the resignation of Dr. Ripley; Dr. Laurence Johnson nominated Dr. A. S. Hunter, and Dr. Carpenter nominated Dr. A. L. Loomis, to fill the vacancy created by the resignation of Dr. Sexton. Dr. Hunter having withdrawn his name, the secretary was instructed to cast an affirmative ballot for Dr. Wylie and Dr. Loomis.

A STATE MEDICAL EXAMINING BOARD.—Dr. STURGIS offered a resolution to the effect that the Medical Society of the County of New York was heartily in favor of the appointment of a State Board of Examiners, before which all future applicants for permission to practice medicine and surgery in this State must appear for examination, as embodied in a bill prepared by the Committee on Legislation of the Medical Society of the State of New York, and that it urged upon the Legislature the necessity for the speedy enactment of such bill.

As some doubt was expressed by several members as to the propriety of recommending any one particular bill, Dr. D. B. St. John Roosa offered the following substitute, which was unanimously adopted:

Resolved, That the Medical Society of the County of New York is in favor of the passage of a bill establishing a State Board of Examiners, who shall determine the qualifications for the license to practice medicine in the State of New York.

Resolved, That this resolution be transmitted to the Legislature of the State, signed by the president and secretary.

THE LATEST RESEARCHES IN EMBRYOLOGY.—Dr. CHARLES HEITZMAN then read a paper with this title, in which he briefly alluded to the views which had been entertained by different observers concerning segmentation during embryological development and the supposed destination of particular segments to the development of given portions of the animal body—views which, it had been supposed, went to support the doctrine of cell-development. This view regarding embryological development and the structure of the body, however, was becoming more and more unsatisfactory to the student of morphology, and lately Stricker had fully adopted the views which Dr. Heitzman had advocated for a number of years regarding the continuity of structure of animal tissues. This view, briefly stated, was that all the structures of the body were continuous; that there were no individual cells within the tissues in the common acceptance of that term; that living matter pervaded both what used to be called cells and also what had been called basement substance or cement substance. Since employing a solution of celluloid in his microscopical investigations, Dr. Heitzman had also been able to show distinctly that from the very moment of segmentation in the embryo the elements remain connected with one another, that the continuity was unquestionably by living matter, that the so-called granules were nothing more than points of intersection of the reticulum and the nuclei, and that they were composed of living substance.

Dr. E. C. SEGWIN testified to the value of celluloid in microscopical examinations, remarking that it constituted a cement which permitted of the most delicate section.

Dr. A. JACOB thought it probable that the apparent difference of opinion between Dr. Heitzman, Virchow, and others, was due in part to the employment of terms which failed to convey a definite idea of their meaning. For instance, Dr. Heitzman had frequently made use of the word *elements*, and it was a question whether it had not been employed to express the same idea which others would convey by the word *cells*.

After a few remarks by Dr. J. L. CORNING and Dr. C. E. NELSON, the discussion was closed by Dr. HEITZMAN, who, in reply to Dr. Jacobi's inquiry, explained what he considered to be meant by the cell theory.

A MEMOIR OF J. MARION SIMS, M. D., LL. D., was then read by Dr. W. GILL WYLIE. As the hour was growing late, Dr. Wylie read only a portion of the memoir. He was indebted largely for his information to an autobiography of Dr. Sims up to the year 1863, not yet published. He traced the history of his operation for the closure of vesico-vaginal fistula, his efforts to establish the Woman's Hospital, and the opposition encountered from a jealous profession, and alluded briefly to his reasons for resigning from the medical board of the Woman's Hospital and to the criticisms which had been offered against him. The author spoke of Dr. Sims's undaunted moral courage, his unbounded enthusiasm, self-reliance, definiteness of purpose, progressive mind, and regularity of habit. He never took wine, coffee, tea, nor condiment of any kind. Before he was attacked with pneumonia, in 1880, he showed great elasticity of body and ability to endure much physical fatigue.

On motion of Dr. W. M. CARPENTER, a vote of thanks was offered the memorialist.

Dr. A. JACOBI read a portion of a letter from Dr. A. Seibert, addressed to the Committee on Hygiene, asking the committee to send a circular to the physicians of New York and Brooklyn, with the request that they note down the exact date of the beginning of every case of primary croupous pneumonia coming under their observation from February 1, 1884, to February 1, 1885, also stating whether the patient at the beginning of the pneumonia was suffering from any catarrhal affection of the respiratory tract. Dr. Seibert's object was to make a collective investigation regarding this disease, but he wished at the same time to avoid the appearance of self-advertisement, and therefore requested that it be done in the name of the Committee on Hygiene, he to bear the expense. It had been stated by European writers that the reverse of what seemed to hold true in America regarding climatology and this disease held in Europe; but Dr. Seibert's studies went to prove, from their own statistics, that the observations of American physicians also held across the water. After some remarks upon the value of the collective investigation of diseases by Dr. Jacobi and the president, Dr. Jacobi's motion that the Committee on Hygiene send out such circulars was unanimously adopted.

NEW YORK CLINICAL SOCIETY.

Meeting of November 23, 1883.

Dr. J. WILLISTON WRIGHT, Chairman for the evening.

FOREIGN BODY IN THE ALIMENTARY CANAL.—Dr. ROBERT ABBE related the case of a child two years of age who had swallowed an English half-penny. He introduced a soft œsophageal bougie, which seemed to meet some obstruction in the lower part of the œsophagus, but finally passed into the stomach. Nothing metallic was felt with the instrument. He ordered the child to be given oat-meal and other dry food, and, four days after, the piece was passed in a mass of fecal matter. It was a little difficult to see how so large a body could pass the ileo-cæcal valve easily.

The CHAIRMAN thought trouble was rarely experienced from

this circumstance. He recalled two cases in which coins in the pharynx had produced distressing laryngeal symptoms by standing up edgewise. The introduction of the finger, and turning the body, had usually made its expulsion by coughing very easy.

EXTRA-UTERINE PREGNANCY.—Dr. J. H. EMERSON read the following history of a case:

"Mrs. G., twenty years old, married three years, had an abortion in February, 1882, at about two months, due, possibly, to her having been knocked down in the street by a horse some three weeks before. Late in the autumn of the same year she missed one menstrual period, but presented no other signs of pregnancy. The uterus was rather under size, with a tendency to retroversion, and a soft ring pessary was worn at times, with benefit. She was also subject to a very moderate degree of leucorrhœa, which the use of hot vaginal douches, sometimes with solution of alum, easily controlled. She was vivacious, active, and fond of society and excitement, and at times over-exerted herself and suffered from backache, which rest or counter-irritation soon relieved. With these exceptions, she was a healthy woman, and led a healthy life. She menstruated last during the last week of August. September 29th, she complained of not feeling as strong as usual, and of having rather more leucorrhœa, and I advised her to take tincture of iron and to use an astringent vaginal injection gently. I also urged gentle exercise out of doors. She remained in the country, and I being in town, her husband reported to me on October 16th that she said the use of the injection had on two recent occasions given rise to a good deal of pain in the back, so that she was unwilling to use it again, although the leucorrhœa was still troublesome. She was now also so timid in regard to exercise, and so easily tired, as to be very unwilling to take any until after the time for the next period, as she believed herself pregnant. The breasts were tender and enlarged. I agreed with him to go to see her on the following day, intending to make a vaginal examination and use whatever local treatment might be required. I received a telegram from her, however, postponing my visit, and subsequently a note saying she felt stronger and was averse to any local treatment at that time.

"I heard nothing further from her until October 30th, when I received a telegram, late in the afternoon, asking me to go to her as soon as possible. I reached her bedside at a little after 7 p. m., and found her in a state of collapse. She had passed the menstrual period, which should have occurred the week before. She had eaten her breakfast on the morning in question, and had felt well enough to engage to dine at a neighbor's. Soon after breakfast she had pain in the 'stomach,' i. e., high in the abdomen, which she attributed to indigestion. Later on this became more severe, and was located much lower down, in the hypogastric region, and rather to the left side. She had also been chilled at times, and often bathed in profuse perspiration. She was slightly nauseated. Through the day there had been three free but not loose movements of the bowels, the urine passing with the stools. There had been no red discharge from the vagina. A local physician had been called in, who had advised small doses of valerian and of carbonate of ammonium. Shortly before I arrived she had taken some beef-tea, the first nourishment of the day since breakfast. When I saw her I found a mere thread of a pulse at the wrist, and the whole body was drenched in perspiration. The extremities were kept warm only by constant rubbing and external heat. She lay upon her left side with her feet rather drawn up; her respiration was shallow, but not very rapid; her mind was perfectly clear, but she made but little complaint of pain. I gave brandy by the mouth at once, also a pellet containing one eighth of a grain of morphine and one one hundred and fiftieth of a

grain of atropine. I then sent for a hypodermic syringe, and gave brandy subcutaneously, and applied mustard and hot fomentations to the præcordia, to relieve the dyspnoea, which was distressing at times. I also wrapped her in hot blankets, etc., but all the effects of these measures were but trifling, and she grew steadily weaker. Between eight and nine o'clock she said there was a flow, and I tried to make a vaginal examination. She was unable, however, to change her position, and I only learned that the uterus was moderately enlarged, and that the bloody discharge was very slight—hardly enough to stain the finger. Nothing could be learned by palpation of the abdomen, owing to her position and the pain caused by very light pressure upon the lower part of the abdomen. She died at 10.30 p. m. An autopsy could not be obtained, and I gave a certificate of death from intra-peritoneal hemorrhage, probably due to rupture of a cyst of extra-uterine pregnancy."

Dr. J. E. WINTERS met with a case last summer in which the symptoms were almost identical with those given by Dr. Emerson. The patient was seized with severe symptoms early in the morning, and died at three in the afternoon. The autopsy showed an ovarian pregnancy, the sac of which had ruptured.

Dr. E. L. PARTRIDGE thought the presence of uterine discharge in these cases not a very important factor in diagnosis. The absence of pain was undoubtedly due to the shock. He hoped to see the time when laparotomy would be attempted in these cases in hospital practice, as this would at least give one chance of life where now the patient seemed to have none.

In response to an inquiry by Dr. Abbe, Dr. EMERSON said he thought the patient would not have borne ether.

HYSTERICAL PERIODICAL RIGORS.—Dr. GASPARD GRISWOLD related the history of a lady who had had regularly for a number of months a chill every Tuesday evening. It was preceded by headache and aching in the bones, and came on between twelve and one o'clock. The chill was severe, was followed by a fever lasting three or four hours, and then a profuse sweat. The temperature had once been taken on the morning following and found to be 104° F., and on another occasion 102.5°. A little malaise, however, was the only thing generally present, and this passed off in a day or so, and the patient was well until the next Tuesday night. On the supposition of malaria, quinine was given in full doses preceding the expected attack. Warburg's tincture was also tried. Nothing had the slightest influence. Pilocarpine hypodermically was next tried just as soon as the premonitory signs of the rigor began to manifest themselves. The attack was aborted by this means, though it was sometimes necessary to give as much as three fifths of a grain before the effects of the drug were produced. On the following week the paroxysm recurred regularly in spite of it. The pilocarpine was kept up for nine successive weeks without any permanent improvement. Bromide of potassium in large doses, once as much as 3 ss. a day, was several times combined with the pilocarpine, but without any change. This had been done because he had become convinced of an hysterical element in the case, although the patient showed no manifestations of hysteria in the interval. At the time of the attack there were constipation and scanty urine—on one occasion slight retention for twelve hours. He raised the question whether it was possible for a patient to have a temperature as high as 104° F. from hysteria alone, as he was now convinced of an hysterical element in the case.

Dr. WINTERS had recently read a report of a series of cases in which periodical chills had occurred. Some were found to depend on gall-stones, some on renal calculus, others on the most diverse causes. None of them had recurred with such regularity and so long as in the case reported.

Dr. NORRIS, who was present by invitation, said a case,

which was regarded by both the visiting and the house staff as one of pure hysteria, was observed in St. Luke's Hospital a few years ago in which the temperature rose repeatedly to 104° F., and even higher. It was carefully watched for a long time.

BRONCHO-PNEUMONIA WITH LOW TEMPERATURE.—Dr. L. E. Holt reported a case illustrating the development of the strumous diathesis after vaccination in a child previously healthy, and, as a sequence of this, an acute broncho-pneumonia which proved fatal in ten days. The interesting features of the pneumonia were the great prostration which attended it and the remarkably low temperature. It had ranged from 99° to 100.5° F. the greater part of the time, and only once rose above 101°, about twenty hours before death.

Dr. WINTERS thought these low temperatures in acute inflammations were not very infrequent in children.

The CHAIRMAN suggested that the inflammation might be analogous to surgical shock, and that the low temperature was from the depression of the nervous system. He thought the development of the strumous diathesis after vaccination was an unquestioned fact, even when the virus was pure.

THE DANGER OF LARGE DOSES OF QUININE.—Dr. A. A. SMITH read a paper on this subject. [See page 115.]

Dr. BEVERLEY ROBINSON entertained similar views as to the inordinate use of quinine, especially in typhoid fever. Its general action was to lower the heart and arterial tension in full doses. He had often been struck with the fact in autopsies that the degeneration of the heart did not bear any constant relation to the height of the fever in febrile diseases. In many cases where the temperature had been high it was slight or absent, while it was often present to a marked degree where the temperature throughout had been low. He was aware that many authorities taught that prolonged high temperature was sufficient to produce cardiac degeneration. He withheld quinine in all cases where there was a tendency to heart failure. In one patient with phthisis, a young lady, who was taking from twenty to thirty grains of quinine a day, syncopal attacks came on repeatedly for which no cause could be found. The quinine was finally stopped, and they were promptly arrested. As quinine had such a decided action on the ear, he always avoided full doses of it in diphtheria, where there was such a tendency to ear complications.

The time for adjournment having arrived, the further discussion of the paper was postponed until the next meeting.

Meeting of December 28, 1883.

Dr. GEORGE L. PEABODY, Chairman for the evening.

ADJUTENED DISCUSSION ON THE DANGERS OF LARGE DOSES OF QUININE.—Dr. J. H. EMERSON asked if any cases were on record in which death was distinctly traceable to the abuse of quinine, and, if so, what lesions had been found.

Dr. A. A. SMITH said he knew of no recorded cases. He himself had seen one, however, and another member of the society had met with one. The bad effects of the drug were produced through the nervous system. Hence no post-mortem changes would be expected.

The CHAIRMAN sustained this view. The heart after high temperature was flabby and in diastole, whether quinine was administered or not.

Dr. SMITH read a report of three cases furnished by Dr. J. W. Wright in which large doses of quinine had produced alarming symptoms. [See page 116.]

Dr. KATZENBACH mentioned the case of a man of sixty-eight who presented all the usual signs of fatty heart. Of late he had suffered from chilly sensations, and sometimes loss of consciousness and slight fever, these symptoms recurring with regularity on alternate days. The friends were convinced that the patient

had malarial disease. He had been taking quinine in tonic doses, and this was increased to gr. xxii a day. These attacks were controlled by the drug, and unpleasant symptoms occurred. He raised the question whether fatty heart or other organic cardiac disease would be any contra-indication to the use of large doses of quinine in malarial fevers.

Dr. SMITH thought a tolerance of quinine existed in all malarial diseases. He thought, however, that in cases like those mentioned it was advisable to administer some counteracting drug to sustain the heart. As stated in the paper, he preferred opium to any other. He would like to ask Dr. Katzenbach whether his patient was taking any other drug than quinine at the time.

Dr. KATZENBACH said he was.

Dr. SMITH asked if it was digitalis.

Dr. KATZENBACH said it was convallaria, but that he attributed very little of the improvement to its use, as the patient had taken it for some time before without any marked benefit.

Dr. L. E. HOLT asked whether Dr. Smith had found any difference in the effects upon the heart of the different cinchona alkaloids.

Dr. SMITH replied that he had never used cinchonidine extensively, but was of the opinion that the danger was about the same in all.

The CHAIRMAN stated, in response to an inquiry, that a number of cases were recorded where quinine had produced death in animals. The cause was usually paralysis of the heart and respiration.

PNEUMONIA WITH GASTRO-INTESTINAL DISTURBANCE.—Dr. SMITH mentioned a case of pneumonia occurring in a man of twenty-two, who had partaken largely of lobster-salad the night before. Six hours later he had a chill, with vomiting and purging. It seemed at first a case of cholera morbus. The temperature rose, however, to 105° F., and the pulse to 140, and physical signs soon declared a pneumonia of the left lower lobe. In the evening of the third day a most intense gastro-intestinal pain developed. It was so severe that the pulse rose to 164, and the patient seemed likely to go into collapse. Morphine was given hypodermically in successive doses, but no relief was obtained until gr. 1½ had been taken. No bad effects were experienced from the drug, and the pulse dropped to 140 and was much stronger. The patient was now convalescent. He attributed the pain to the lobster-salad.

Dr. ROBINSON raised the question of the use of opium in extensive lung and renal disease. It had seemed to him that it often produced bad symptoms in both conditions. Although there was little doubt that opium under many circumstances was a powerful heart stimulant, he questioned its utility in any case where the lung was disabled to an extreme degree, but particularly in acute phthisis. On three or four occasions this winter he had seen, in cases where opium seemed indicated, such patients made worse, and even cyanotic, from its use.

In a case of advanced nephritis which he had just seen, in which the patient was suffering from absorbed pus, probably from the kidney, although small doses of morphine had controlled the vomiting, it had seemed on the whole to do harm. He asked the experience of the society on the subject.

Dr. SMITH thought opium invaluable in all acute lung diseases. The special indications for its use were pain, marked restlessness, and a dry skin. He had used morphine, the deodorized tincture of opium, and paregoric, and hardly knew which preparation was the best in these cases. In chronic phthisis it was useless as a cardiac stimulant, but valuable to allay the cough, etc.

In advanced renal disease it was capable of doing a great deal of harm.

SPASMODIC STRICTURE OF THE OESOPHAGUS.—Dr. D. BEYSON DELAVAN related the following case: The patient, a lady of forty, was struck in the neck about a year ago by a carriage-pole while crossing a street. She was knocked down, but received no serious injuries. Some swelling and ecchymosis occurred at the side of the neck, the seat of the blow. She now suffered from great difficulty in deglutition, which was marked at the upper end of the oesophagus. When this point was passed the act was easy until just before the bolus passed into the stomach. An oesophageal bougie passed easily into the stomach. On attempting, immediately after, to swallow a glass of water, the spasm was marked. She was despondent, having been treated in various ways without benefit. He prescribed the mixed bromides in gr. x. doses three times a day. After a week the spasm disappeared, and had been noticed only once since that time. She had now been under treatment three weeks. He mentioned a case he had seen reported recently which had resisted all treatment until the uvula, which was much elongated, was amputated. Prompt disappearance of the spasm followed. In his own case the uvula was normal.

ERYSIPELAS AFTER VACCINATION.—Dr. HOLT mentioned a case of erysipelas occurring six weeks after vaccination, the ulcer being at the time not quite healed. The case presented some unusual features at the outset, the blush not appearing until the third day. He raised the question of the relation of the two diseases.

Dr. F. P. FOSTER thought the relation was not nearly so close as was generally supposed. There was nothing special about a vaccine wound or a vaccine ulcer which rendered the patient liable to erysipelas. It occurred about these as about other wounds and ulcers. He had been impressed with this fact by a case mentioned to him some years ago by Dr. S. S. Purple. A day had been set for vaccinating a child, but for some reason it was postponed. Precisely eight days thereafter the child was taken with erysipelas at the left deltoid insertion, and died.

Dr. HOLT referred to some cases which had been recently reported in the "British Medical Journal" in which erysipelas was communicated by vaccination. A child, whose arm showed no signs of the disease, furnished lymph from which two others were vaccinated. In a few days it developed erysipelas, and died. Both the other children had erysipelas, and one died.

Dr. FOSTER did not wish to be understood as saying that erysipelas could not be communicated by vaccination. In the cases alluded to, and in others with which he was familiar, the transmission was undoubted. He had known scarlet fever to be communicated to the vaccinee while the vaccinator was still in the incubative stage. The fact that this was possible was enough to condemn the practice of arm-to-arm inoculation.

L. EMMETT HOLT, M. D., *Secretary.*

NEW YORK MEDICAL AND SURGICAL SOCIETY.

A **STATED** meeting was held December 8, 1883, Dr. THOMAS F. COCK chairman for the evening.

RAPID DEVELOPMENT OF HYDROCELE.—Dr. A. C. POST said that a man came to his clinic the day of the meeting with a large swelling of the scrotum, said to have developed within the past two months. It was unattended with pain or disturbance of the general health. The tumor, which was larger than the fist, was found to be a hydrocele. From eight to eleven ounces of fluid were withdrawn, and a mixture of half a drachm each of carbolic acid and glycerin was injected. Dr. Post had never before known a hydrocele to develop to such a size in two months.

CONGENITAL INGUINAL HERNIA, COMPLICATED WITH UNDESCENDED TESTICLE; REMOVAL OF THE TESTICLE, FOLLOWED BY APPARENT CURE OF THE HERNIA.—Dr. F. N. OTIS related the following case: Not long since, a farmer, about thirty-five years old, had been sent to him by Dr. Fanning, of Stony Brook, Long Island, complaining of great difficulty in wearing a truss for inguinal hernia. The trouble was found to result from the presence of an undescended testicle. He stated that, from infancy, there had been a slight swelling in the inguinal region. But little was done for it until he was twelve years old, when a physician discovered that it was a hernia, and, reducing it easily, applied a truss. This caused a good deal of pain, and it was then found, on closer examination, that there was only one testicle in the scrotum. The other one was discovered just below the external ring, and was movable, but it was not situated low enough, and could not be pushed up high enough to allow of the use of a truss without pain. The hernia was of considerable size.

When the man consulted Dr. Otis, November 13, 1883, he was considerably reduced, and had an expression denoting habitual suffering. He said he had tried various kinds of trusses, but they all produced intolerable pain if worn continuously for more than a few hours. The hernia always protruded to the size of a hen's egg on the slightest departure from the horizontal position, but it was readily reduced, the ring being very large. The testicle was found lying on the aponeurosis of the external oblique muscle, between it and the superficial fascia, and movable, from an apparent point of attachment at the border of the external ring, nearly three inches downward—to just within the scrotum, and upward to a point opposite the anterior superior spine of the ilium. It was somewhat atrophied, being about an inch by three quarters of an inch in its diameters, and quite sensitive on pressure. The patient was very desirous of having it removed and the hernial opening closed at the same operation. He had been married several years, and his only child was three years old.

Dr. Otis believed that the testicle was of little use, and that it would be entirely proper and safe to remove it, as it apparently had no direct connection with the peritoneum. He was not so much inclined to operate on the hernia at the same time, however, and he asked that Dr. Markoe be called in consultation. Dr. Markoe agreed with him entirely. Rather more than three weeks ago he removed the testicle. It was pushed up as high as possible, and out toward the border of the ilium. On cutting through the skin and the superficial fascia, the testicle protruded with its coverings. The cord was readily drawn out to the extent of about two inches and a half, and was secured while excision was performed. The vessels, evidently considerably atrophied, were then tied. There was but little hemorrhage. The wound was sponged with a solution of bichloride of mercury (1 to 1,000), and a carbolized-gauze compress and a spica bandage were applied. The patient had been subject to attacks of vomiting at times, and on such occasions he had been unable to retain the hernia within the abdomen by any means. He vomited a good deal after coming out from the effects of the ether, considerable pain was complained of, and, on removing the bandages, the hernia was found to have descended. It was easily reduced, the compress was replaced, and the patient did perfectly well for nine days. On the tenth day he was permitted to get out of bed and lie on a lounge near by. Immediately on doing so he complained of pain near the external ring, the point to which the cord had probably retracted. There was tenderness, followed by swelling, and the temperature ran up to 102° F. The wound had healed completely, the stitches having been removed on the sixth day. The swelling referred to reached to about half the size of a pullet's egg, and

on the thirteenth day, just before the time set for opening it, the pus was discharged from the lower edge of the wound. The temperature then fell, the wound healed up, and the man was now about, wearing a truss and feeling well. It had been noticed that the patient's general condition was one favoring suppuration, as manifested by the occurrence of an alveolar abscess, which required the removal of a defective tooth. To counteract this suppurative tendency, sulphide of calcium was given, in doses of a tenth of a grain, every half hour. About two ounces of pus escaped from the inguinal abscess, and warm applications were employed. There was no more suppuration, adhesion of the walls of the abscess took place promptly, and the associated induration disappeared within a week. It was found that the external ring had been closed completely by the inflammatory exudation consequent upon the formation of the abscess; neither standing nor coughing caused any hernial protrusion. However, the truss was recommended to be re-applied and worn for some weeks, and the patient, apparently well in every respect, was sent home.

There appeared no good reason in this case why an early operation should not have saved the patient years of suffering. In the fourth edition of Curling's work on "Diseases of the Testicle" (London, 1878) the following case would be found, bearing on this point:

"In the spring of 1858 W. M., aged thirty-one, came under my care at the London Hospital in consequence of suffering pain in the right groin when lifting heavy weights. I found the seat of pain to be a small testicle in a closed sac, containing two or three drachms of fluid, situated just outside the abdominal ring. I advised the removal of the organ, but, the patient having lost all pain during rest in bed for a few days, and the swelling having diminished, he declined the operation, which I did not press upon him. He again applied to me some months afterward, on account of pain and increase of the hydrocele in the groin, but, as it subsided under rest, he still refused to submit to an operation. The frequent recurrence of pain after active exertion at length became so annoying that in October, 1859, he requested me to excise the testicle, which I did. The organ was small and inclosed in a sac which extended up to the inner ring, but did not communicate with the peritonæum. He recovered quickly, and was completely relieved. The left testicle was in its proper position in the scrotum.

"Stromeyer, the distinguished German surgeon, sent me the particulars of a case of inguinal hernia, complicated with detained testicle, in a nobleman aged twenty-three. A truss could not be borne, and the patient could neither dance nor ride on horseback, a state which formed a great obstacle to his career. Stromeyer, in 1841, proposed an operation, which was to consist either in the separation of the bands which kept the spermatic cord in its shortened state, or eventually in the removal of the testicle. The operation was objected to. Twenty years later he was called to this nobleman, in consequence of his being in great danger from an incarcerated hernia, which was relieved without operation. It appeared that he had been treated by Larrey and Cloquet for similar attacks, and, as Stromeyer remarked, the patient would have been saved twenty years' pain and misery if the testicle had been removed in his youth.

"The excision of the testicle was performed, in 1845, in a case of retained testicle with hernia, related by Gosselin. It occurred at the Hôtel Dieu, in the practice of Blandin. The patient had suffered severely since the age of fourteen, and became so much discouraged by the repeated attacks that, at twenty-eight, he desired to have the testicle removed. Blandin would not consent to the operation, and tried a truss applied above the testicle, with the view of fixing it. During the following eighteen months the patient was frequently troubled, and had an attack of strangulation, which was relieved by the taxis, and also orchitis with acute inguinal hydrocele. Seeing no end to his sufferings, he insisted on the removal of the testicle, which was done, with complete relief. The vaginal sac was found distinct from the hernial sac.

"These cases are related that, under similar circumstances, the sur-

geon should not hesitate to advise the removal of a retained gland which is very rarely capable of performing its proper functions."

OVER-DISTENSION OF THE BLADDER MISTAKEN FOR AN OVARIAN TUMOR: ESCAPE OF A CATHETER INTO THE BLADDER.—Dr. T. A. EMMET had received a letter one Sunday afternoon asking him to meet the writer as soon as possible in consultation regarding a case of ovarian tumor which had existed some six or eight weeks. Dr. Emmet remarked, on receiving the letter, that he could not imagine how an ovarian tumor could develop to a marked size in so short a time. The following Wednesday afternoon was fixed for the consultation, and, when he was about to enter the room, a young physician from the neighborhood met him, having been called in hastily while the woman was in convulsions. He said that, as the patient had not passed much water during the day, he hastily put together the two sections of a silver catheter which he had in his pocket, not having the third section with him, and began to draw off the urine. About a quart having escaped, he turned to empty the vessel, when the catheter was sucked from between his fingers up into the bladder. Dr. Emmet found the woman in deep coma. The abdomen was enormously distended, as much so as in any case of ovarian tumor which he had ever seen. The walls were so tense that he could scarcely obtain fluctuation, although it was evident that the distension was due to fluid. He sent out for an elastic catheter, with which he emptied the bladder, whereupon the tumor disappeared. An enormous amount of urine was withdrawn. After the bladder had been emptied, the silver catheter was felt projecting against the abdominal walls as through an ordinary sac. He had little difficulty in removing it with the forceps unobserved. It seemed that before Dr. Emmet saw the patient she had been about the house, and there had been some vesical irritation, supposed to be due to the presence of an ovarian tumor. She was about thirty-four years of age. This was the second case that he had seen in which the catheter had been sucked up into the over-distended bladder during catheterization, and he asked if there was any explanation of a tendency to this accident in this condition. The case was interesting also from a diagnostic point of view. The patient had been going to the closet oftener than usual for nearly two months, passing a little water each time, but there was constantly developing a greater degree of vesical distension, which had been mistaken for an ovarian tumor by one who, under ordinary circumstances, certainly would not make a mistake regarding a tumor of the ovary. Dr. Emmet thought that, as a specialist, he himself might have been misled as to the true condition. He was told that the patient finally died in an apoplectic seizure, the result of renal disease.

Dr. Post said that he had once been called to make a post-mortem examination in the case of a female child, four or five years of age, supposed by the attending physician to have been suffering with incontinence of urine. He found the bladder enormously distended with urine, and extending as high up as the umbilicus.

VESICAL AND URETHRAL IRRITATION IN RETRO-UTERINE CELLULITIS TREATED BY "BUTTON-HOLING" THE URETHRA.—Dr. EMMET also presented the histories of two cases which led to the following remarks: By accident he had noticed that in certain cases, calling for his operation of button-holing the urethra, vesical irritation, which had previously existed, had been relieved, and cellulitis, existing in the region of the utero-sacral ligament, had been rendered easy of treatment. Many women suffered from vesical irritation to such a degree that they became opium-eaters for the relief of pain, and the cause was found to rest in an intractable cellulitis posterior to the uterus. If allowed to go on, they not only became confirmed opium-eaters, but what at first was only an irritation would finally result

in an inflammation of the bladder and of the kidneys, and in death. During the past autumn he had treated as many as five or six cases of vesical and urethral irritation by making a button-hole opening into the urethra, which speedily resulted in relief of this symptom, and enabled him to treat the retro-uterine cellulitis successfully. The operation might seem a heroic one for so simple a condition as urethral irritation, but it was by no means so formidable as it might appear; moreover, it was for the relief of a symptom which was liable to lead to the more serious conditions already referred to. If the opening were not extended up into the neck of the bladder, incontinence of urine would not result, the patient would have no trouble in passing the urine, and, indeed, he seldom had an opportunity to close the opening again, as the patients experienced no inconvenience from it during micturition.

In reply to a question as to the *rationale* of the treatment, Dr. Emmet said it was probable that the pelvic cellulitis caused exudation and adhesion, which produced more or less traction upon the structures connecting the urethra with the pelves, and that the operation relieved this traction, thus permitting freer circulation in the pelvic tissues. Whatever might be the true explanation, the clinical fact was beyond doubt, as he had witnessed in as many as twenty cases, and the operation had come to be a common one with him in the treatment of cases of vesical irritation with inflammation behind the uterus.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

(Concluded from page 112.)

NITRO-GLYCERIN AND THE CHLORIDE OF GOLD AND SODIUM IN THE TREATMENT OF ALBUMINURIA.—DR. BARTHOLOW also read the following paper:

Hitherto the therapeutics of renal diseases has not advanced in the same ratio as our knowledge of their pathology. It can not be said now that a cure has been found, but that two remedies of real value are available. My contribution to this symposium on albuminuria consists in an attempt to define the place which these remedies should occupy in a curative scheme. To do this, in even the briefest way, I must clear the ground with a preliminary statement.

I start with the proposition that those renal lesions united by the common symptom—albuminuria—are of neural origin. There is a kinship between diabetes and Bright's disease. One of these is sometimes substituted for the other; and during the course of some rare cases of exophthalmic goitre this substitution occurs. Irritation of a certain part of the floor of the fourth ventricle is followed by glycosuria; of another part by albuminuria. The recent observations of Da Costa and Longstreth prove that a relation exists, whether casual or sequential, between certain renal lesions and degenerative changes in some ganglia of the abdominal sympathetic. The hypertrophy of the muscular coat of the arterioles, discovered by Dr. George Johnson, and the increased tension of the vascular system due to an irritation of the vaso-motor center in the medulla, both present in the chronic forms of albuminuria, are further evidences of the agency of the nervous system. It was, more especially, the condition of elevated tension of the vessels which led to the use of nitro-glycerin. This remedy before all else reduces the vascular tension. It also lessens the work of the heart by removing the inhibition exercised by the pneumo-gastric nerve.

This remedy appears to have been first used by Mr. Robson, an English surgeon, in cases of albuminuria, and by him employed, because the high tension of the vascular system has proved to be so pronounced an element in the more chronic cases. I have myself seen some remarkable instances of relief

—indeed of cure—effected by it. If time were now available, I could give some striking examples. In cases of mitral disease accompanied by albuminuria it also renders the highest service, for the diminished peripheral tension lessens the work to be done by the heart, and assists in the more equal distribution of the blood. The effect of this in relieving the renal congestion is obvious.

Chloride of gold and sodium has quite another function. It has long been known that this remedy has a special direction to the genito-urinary apparatus. The ovarian and uterine organs in the female, the testes and vesiculæ seminales in the male, are stimulated by it, and the kidneys, by means of which it is eliminated, and in which it tends to accumulate, are decidedly affected by it in function and structure. In common with some other agents of the class to which gold belongs—for example, corrosive sublimate—the chloride acts on connective tissue and checks its over-production, or its hyperplasia. It would be quite impossible in this note to go over the evidence on these points, and hence I must ask your assent to these statements. They have been accepted as true of gold, from the days of the alchemists and iatro-chemists, as any one may ascertain from that curious collection of mediæval medical learning—the “Anatomy of Melancholy.” It has happened, strangely enough, that Hahnemann and his followers have profited by this knowledge, and have used gold preparations—especially *aurum potabile*—in the treatment of renal diseases with success.

How and when are these remedies to be used?

Nitro-glycerin is now administered, as all present know, in the form of the centesimal solution—1 minim of the pure drug to 100 minims of alcohol. The initial dose of this one-per-cent. solution is one minim, which should be increased until the very characteristic physiological effects are produced. The susceptibility to the action of nitro-glycerin varies greatly, and hence the dose can not be stated in advance. It is necessary to produce some obvious effect. To maintain the same level of action, a slight increase in the dose may be required from time to time. As the effect is not lasting, the interval between the doses should not exceed three or four hours.

The administration of nitro-glycerin should begin in acute cases immediately after the subsidence of the acute symptoms. It is indicated in chronic cases at all periods, but is more especially useful if given before hypertrophy of the muscular layer of the arterioles has taken place. When it acts favorably, the amount of albumin in the urine steadily diminishes. The mechanism of its action consists in the lowering of the pressure in the renal vessels. How far any curative effect proceeds from action of this remedy on the sympathetic system remains to be determined.

Chloride of gold and sodium is indicated in the subacute and chronic cases, especially the latter. The earlier it is given the better, if structural changes are to be prevented or arrested. The good effects to be expected from it will depend necessarily on the extent of the damage already inflicted on the kidneys.

The usual dose is $\frac{3}{16}$ grain twice a day, but this may be much increased if necessary. At the outset, $\frac{1}{16}$ grain may be given; in a week the dose should be lowered to $\frac{1}{32}$ grain, and after a month the regular dose of $\frac{1}{16}$ grain should be steadily pursued, with occasional intermissions. Indigestion, gastralgia and colic pains, nausea or diarrhœa, are occasionally caused by it; and, if so, the quantity administered must be reduced. It is usually borne without any discomfort, but, after prolonged administration, salivation, weakness, emaciation, trembling, and other nervous phenomena may occur possibly. Such effects, however, are wanting in my experience.

The treatment of albuminuria by nitro-glycerin and the chloride of gold and sodium does not necessitate the exclusion

of other means—hygienic, climatic, or dietetic. These remedies should, however, be given uncombined at different hours, and their actions should not be hindered or obscured by the effects of other agents given with like purpose. To this general statement there may be two exceptions: with nitro-glycerin, amyl nitrite or sodium nitrite may be given; with the gold-and-sodium chloride, corrosive sublimate may be combined. If doubts may be felt in regard to the propriety of depending on the utility of these remedies, they need not be long experienced, for, if no good effects are observed in two weeks, they may then be discontinued.

THE SUPPOSED CONNECTION BETWEEN EAR DISEASE AND KIDNEY DISEASE.—Dr. CHARLES H. BURNETT read the following paper:

Early writers on disease have shown a knowledge of the fact that alterations in hearing occur in the course of general diseases—as, for example, in diseases of the kidneys. It was supposed by them that the alteration in the functions of the ear, in this form of disease, was due to changes in the auditory nerve. But the results of the more reliable modern investigations tend to show that, if an ear disease be due to a kidney disease, the lesion usually occurs in the tympanic cavity and not in the auditory nerve.

Certainly accidents of a hæmorrhagic or apoplectic form nature might be expected either in the tympanic cavity or internal ear in Bright's disease, when we reflect upon the deterioration of the blood, and upon the malnutrition and friability of the vascular system, in the later stages of the malady. Further, as Bright's disease is characterized by a tendency to inflammation, especially in serous membranes, and as the membranous structures of the internal ear, or labyrinth, belong to this class of membranes, very naturally organic change in these tissues might be looked for in Bright's disease of the kidneys.

However, as late as 1856, Rau, in his "Ohrenheilkunde," published in Berlin in that year, claimed that there was not a solitary reliable observation at that time on record in favor of any symptomatic relation between the ear and the urinary organs.

In 1869, Schwartz* reported a case of extravasation of blood into the tympanum, as peculiar to Bright's disease, though of rare occurrence, and, in the same year, Dr. G. M. Smith, of New York,† "called attention to the fact that impairment of hearing was at times one of the symptoms of Bright's disease, and a symptom which could not be explained by referring it to uræmia."

In 1873, Dr. Roosa, of New York, in his treatise on the ear, refers to an obstinate case of suppuration and pain in the middle ear in a man, sixty-one years old, suffering from Bright's disease. In this case it was supposed that the effect of the renal disease upon the tympanic vessels was the cause of the acute suppuration, and it was also supposed that the disease in the drum cavity was originally hæmorrhagic in nature. The subject was deemed of enough importance to place a physician on his guard for renal disease in cases of hæmorrhage into the tympanic cavity.

It must not be forgotten, however, that there is a purely sthenic form—otitis media hæmorrhagica—occurring in subjects entirely free from kidney disease, in which the only effusion is pure blood, the removal of which from the tympanum by paracentesis is followed by cessation of pain and return of hearing.‡

Again, in 1878, Schwartz* states that serous catarrh of the tympanic cavity is found in syphilis, heart disease, pneumonia, Bright's disease, naso-pharyngeal catarrh, and apparently may be due sometimes to vaso-motor disturbances. The same author says hæmorrhages into the labyrinthine cavity and the membranous labyrinth occur in kidney diseases.

Also, that extravasations of blood into the tympanum (hæmato-tympanum) occur spontaneously with acute inflammations in morbus Brightii, cynanche diphtheritica, and in endocarditis verrucosa recens et ulcerosa (*op. cit.*, p. 94).

Dr. Paul Pissot,† in an inaugural thesis, is disposed to consider three forms of aural disease, which may arise in Bright's disease, viz.: tinnitus aurium, partial deafness, and complete deafness. His conclusions are that affections of the hearing may arise at the beginning or during the course of the renal disease. Intermittence seems to be characteristic of these forms of deafness, which may be contemporaneous with the oedema, or may precede it. They appear with all forms of the disease, and are manifested with variable intensity. But he can not say to what special lesion of the ear, or of the nerve of hearing, their symptoms are attributable. Delacharrière, a responsible aurist, examined the cases upon the history of which the thesis is based, and found rupture of the membrana tympani, abnormal vascularity of the manubrium, and sclerosis of the tympanum, and was disposed to regard the conditions as causative forces. Pissot held that the hypothesis of Rosenstein, according to which there is oedema in the course of the auditory nerve within the cranium, may explain the intermittence and variations of intensity in these morbid manifestations. This latter process may be analogous to the oedema of the glottis and vocal cords noted in Bright's disease by Fauvel, in 1864. A similar symptom has been noted by Sée.

In alluding to chronic, non-suppurative aural catarrh in children, von Troeltsch‡ says: "A greater blood pressure from increased action of the heart, as in Bright's disease, must necessarily produce a certain hyperæmia, even in the mucous membranes of the head."

Albert H. Buck,§ of New York, expresses the opinion that in some instances a serous fluid, deeply tinged with the coloring matter of the blood, finds its way into the tympanic cavity through other than inflammatory causes. "Instances of the latter form of disease are very rarely met with, and then usually in connection with a depraved state of the general nutrition, as in morbus Brightii."

Dr. Maurice Raynaud|| expresses the opinion that diabetic otitis is not only more frequent than is supposed, but that, when this has once become a well-known fact, it may prove a pathognomonic index, like anthrax, diffuse phlegmon, and certain erythematous eruptions about the genitals, and arouse suspicion of the presence of the renal disease hitherto unsuspected. He cites a case of well-marked diabetes mellitus in which there suddenly occurred, one evening, a severe earache, after the patient had been in the hospital two weeks, and most carefully watched, so that no chilling could have been the cause of the ear pain. The pain became intense, and toward midnight of the same evening in which the pain set in there occurred an abundant hæmorrhage from the

drum-cavity of the affected ear, which was followed by immediate relief. This was followed for several days by a copious sero-sanguinolent, and then serous discharge, which contained leucocytes and albumin, as shown by heat, but no sugar. Post-mortem examination, twenty-three days after the attack of otitis, revealed a large perforation in the anterior segment of the membrana tympani, red, fungous, and bleeding mucous membrane in the drum-cavity, in which there was a pink, purulent liquid. The ossicles were not dislocated, but were imbedded in granulations, and near the stericp was a clot of blood. The mastoid cavity was filled with a rose-colored liquid, containing pus-cells, and its bone substance was greatly injected and marbled, presenting all the appearances of inflammation of bone tissue. The labyrinth showed no alterations. The author concludes that otitis in the petrous bone is a peculiar and constant symptom of diabetic otitis.

P. McBride,* in an article devoted to the consideration of the various causes leading to aural disease, states that "occasionally the ear is affected in Bright's disease by hemorrhage into the tympanic cavity. The tympanum becomes filled with blood, which probably either becomes absorbed or leads to suppuration. Schwartz was perhaps the first to observe this condition." McBride further says: "I am not aware that sudden labyrinthine deafness in the course of Bright's disease has been described, but it seems probable that such a contingency might be looked for here and also in pernicious anemia, in which retinitis hemorrhagica is not uncommon."

In the recently published work of Professor Politzer† on the ear, the author's experience is that, in cases in which a supposed connection existed between the organic renal disease and an aural malady, the fundamental cause lay in very apparent changes in the middle ear. He has also found that "catarrhs of the ear run an unfavorable course in tuberculosis, Bright's disease, and all cachexie by which the nutrition of the general system has become deteriorated."

Conclusions.—1. Evidences in favor of either frequent or well-marked aural lesions, dependent upon renal diseases, are extremely meager.

2. Those lesions in the ear which have been found in connection with Bright's disease and diabetes mellitus, and which may have been dependent upon the dyscrasia induced by these renal disorders, are in the form of sero-sanguinolent and hemorrhagic effusions into the drum-cavity. But the latter must not be mistaken for the sthenic form of otitis media hemorrhagica.

3. From the serous nature of the membranous structures of the labyrinth, organic changes might reasonably be expected in Bright's disease, but positive proof of the occurrence of such lesions based on ante- and post-mortem history is wanting.

OPHTHALMOLOGY.

By CHARLES STEEDMAN HILL, M.D.

LECTURE ON OPHTHALMOLOGY AND ORBITAL IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, SURGEON TO THE NEW ARMY AND NAVAL DISPENSARY; OPHTHALMOLOGIST TO THE U.S.A. & FREE HOSPITAL FOR CHILDREN AND OF THE SOCIETY AND CHILD'S HOSPITAL.

NEURASTHENIC ASTHENOPIA AND SO-CALLED ANESTHESIC RETINÆ.—Wilbrand's paper is an exhaustive résumé of a sub-

ject that has been much discussed ("Arch. of Ophth.," xii, 3 and 4). The object of the paper is to show: 1st. That in neurasthenic patients, along with copious disturbances, we find all grades of symptoms of so-called anæsthesia of the retina. 2d. That these symptoms, on the part of the nervous elements of the eye, are due to the same causes as are the analogous symptoms manifested by the same patient in other parts of the body. 3d. That it is a mistake to regard anæsthesia retinæ as an independent pathological condition. The most prominent symptom in cases of neurasthenic asthenopia is the peculiar form of contraction of the field of vision more toward one side than the other. The duration of the attacks of obscured vision is usually but a few minutes, and it is very difficult to fix the precise degree of diminution of vision, which shows extreme fluctuations. There is marked inability to use the eyes for any length of time at close work. There are occasional diplopia and transient, slight ptosis.

A PECULIAR ANOMALY OF THE OPTIC NERVE.—Purtscher ("Arch. of Ophth.," xii, 3 and 4) reports a case of a peculiar condition of the optic nerve in one eye of a young man aged twenty. The anomaly consisted in the sudden elevation of a sector, and especially of the vessels of this part, almost two thirds of a millimetre above the normal level. The image of the lower part of the optic nerve resembled that of choked disc, but any pathological condition was excluded by its monocular character, and especially by its limited extent; moreover, all the functions of the eye were perfectly normal.

A CASE OF ECTOPIA OF THE EYEBALL BY OSTEOPHYTES FROM THE ROOF OF THE ORBIT.—Birnbaeh's case ("Arch. of Ophth.," xii, 3 and 4) is rare. It occurred in a young man, aged seventeen, who in early youth had suffered from hydrocephalus. The right eyeball was displaced downward and outward from its normal position by osteophytes growing from the upper wall of the orbit as a sequence of disease of the frontal sinus, under which, through absorption of the walls of the frontal sinus, an emphysematous tumor afterward appeared in the region of the eyebrow. These osteophytes were removed by an operation through the lid, the line of incision being made horizontally through the lid and parallel with the upper orbital margin. The bony combs were loosened and removed by the chisel, and the roof of the orbit and interior of the frontal sinus carefully smoothed by the rasp. The result was satisfactory.

OCULAR LESIONS AFTER INJURIES OF THE BRAIN AND SPINAL MARROW.—Nieden's article ("Arch. of Ophth.," xii, 3 and 4) is of considerable interest. His first case was one of fracture of the base of the skull, amaurosis of the left eye, temporal hemianopsia and paralysis of the external rectus muscle of the right eye, and supposed partial rupture of the chiasm. As there was abolition of the hearing power on the same side, there was probably a fissure extending from the middle of the sphenoid into the petrous portion of the right temporal bone, implicating that part of the abducens nerve of the same side which passes through the cavernous sinus. The second case was a perforating wound of the left temporal bone, paralysis of the left abducens nerve, right hemiplegia without loss of sensibility, and sensory aphasia. The assemblage of symptoms exhibited by the patient points to a direct injury of that part of the cortex comprising the gyri centrales and the paracentral lobule. The third case was one of concussion of the brain and spinal cord, followed by progressive spinal ataxy, exophthalmus of both eyes, and atrophy of both optic nerves. This case ended in a slow improvement of the general condition.

THE EYE DISTURBANCES IN TABES DOSSALIS.—Schmeichler ("Arch. of Ophth.," xii, 3 and 4) has quite an exhaustive article on this subject. In the beginning of the process, when

**Edinb. Med. Jour.*, February and March, 1882.

† Cassell's English Translation, Philadelphia, 1885.

vision is but slightly diminished, no change is found aside from the discoloration of the papilla. If the process has already reached a certain intensity and the visual power is considerably diminished, the vertical vessels are found intact, but sometimes the transverse vessels are found in fewer number. If the atrophy be already far advanced, one or more veins are seen to be wider than normal. After a duration of the optic nerve atrophy for years, the papilla is often found decreased as a whole and the vessels narrowed. The acuteness of vision is not in direct proportion to the ophthalmoscopic appearances. If the atrophic process has begun, the visual acuteness sinks within a few months to a minimum, decreases gradually till only quantitative perception remains, and ordinarily remains stationary at this point; rarely does complete amaurosis occur. The condition of visual acuteness in tabes differs from that of multiple sclerosis in sinking much lower. The characteristic visual field is the one with concentric limitation. In tabes the entire optic nerve is uniformly affected. The most peripheral portions of the retina, which also normally have a lesser visual power, become functionally disabled at the beginning of the disease; afterward, those nearer the center. A very important diagnostic feature is color-blindness, or rather insensibility to color. Not the slightest vascular disturbance has ever yet been found with beginning tabetic atrophy with good visual power. The pathological process in tabetic atrophy begins simultaneously in the nerve, chiasm, and tract, or it affects the peripheral segment. With the atrophic process, the part of the optic nerve over the lamina cribrosa shrinks to a thin layer of fibrous tissue. The arteries remained unchanged, but the veins gradually expand to fill the space caused by the shrunken nervous tissue. The disturbances of the pupil in tabes are: 1, reflex iridoplegia; 2, absolute iridoplegia; 3, myosis; 4, inequality of the pupils. By reflex iridoplegia is understood the lack of pupillary reaction to light; with total iridoplegia, the reaction on convergence is also absent. By spinal myosis is meant the narrow pupil found with disease of the spinal cord. The pupillary inequality is a very striking symptom; of all changes in the pupil it is the most frequent. The disturbance of the ocular muscles in tabes consists in paresis of one or several. It begins almost always with the very first symptom of tabes, but may precede it by many years. It very frequently appears suddenly, though it usually develops gradually. It may remain constant, or may disappear after several months, leaving no trace behind. The path of tabetic sclerosis is determined by the course of the arterial vessels. This particular paralysis is met with in no other form of spinal disease.

A CASE OF RIGHT-SIDED HEMIOPHIA AND NEURO-RETINITIS, CAUSED BY A GLIOSARCOMA IN THE LEFT OCCIPITAL LOBE.—FANCY ("Arch. of Ophthal.," xii, 3 and 4) reports a case of this nature occurring in a woman aged twenty-one. When he first saw the patient she could barely count fingers at 8' eccentrically with the left eye, and here the field of vision was contracted in its upper, lower, and outer portions, and absent altogether in its nasal half. In the R. E. V = $\frac{3}{8}$, temporal half of field absent and field impaired upward, inward, and downward. The optic discs were swollen and dirty-white in color. The movements of both eyes were normal, as were also the general sensibility and motion of the extremities. The existence of a tumor at the origin of the optic nerve seemed the most plausible diagnosis, and this was supported by the absence of motor paralysis and by the pain felt in the occipital region. The patient died comatose in about a month, the coma having been preceded by convulsions. At the autopsy, the dura mater was adherent to the left occipital lobe in one place, which represented an hemispherical prominence above the surrounding level about 3 cm. in diameter. At the corresponding part of the skull there was

a smooth depression which penetrated the entire thickness of the bone. The posterior portion of the left hemisphere showed also a considerable depression, which occupied the posterior portion of the parietal lobe and the whole occipital lobe. It extended forward to the vicinity of the posterior central gyrus. The depression was caused by the evacuation of several tablespoonfuls of a clear, yellowish fluid when the brain was taken out. The above-mentioned prominence of the left occipital lobe was of a reddish-yellow color, soft and smooth. The tumor extended forward close to the parieto-occipital sulcus. On the median side the tumor was firmly connected with the pia, was of a pale-gray color, and adhered partially to the cerebral substance. A sagittal section of the hemisphere through the middle of the tumor showed immediately below the latter a large cavity surrounded by a smooth, transparent membrane. The cyst had a diameter of 8 cm. in length by 8 cm. in width. From the lower wall of the cyst a membranous cord ran through the cyst like a bridge, and was apparently attached to the region of the external tumor. At the external prominence the wall was occupied by a tumor, 2 cm. in thickness, soft, pale, of a transparent, reddish-gray color. In the center of this tumor was a large, dark-red and soft nodule, as large as a hazel-nut, which merged into a large quantity of vascular villi connected with each other by a loose neoplastic substance. The great ganglia, thalamus opticus, corpus striatum, nucleus lenticularis, chiasm, and optic tracts were unaltered. The tumor was a soft gliosarcoma, and most probably started from the interior of the occipital lobe in the vicinity of the posterior cornu, perhaps from the ependyma, and grew gradually toward the surface. The broad, longitudinally folded band which passed through the cyst was denser than the inner lining of the cavity. The case is interesting for the reason that the cerebral tumor, having existed probably for years, remained perfectly latent for so long a time. Besides the hemianopia, no additional symptoms of a circumscribed brain disease were developed until the fatal issue.

THE REPRESENTATION OF THE LIMITS OF THE VISUAL FIELD.—Hilbert ("Arch. of Ophthal.," xii, 3 and 4) considers that visual fields mapped out on the board are the most serviceable to practitioners. A perfectly correct representation of the configuration of the visual field is possible only when it is registered on the perimeter of Scherk. He regards the visual fields entered on perimetric charts as distortions. He thinks that the angles belonging to a visual field mapped out on the board may be computed without difficulty, and that a visual field given by a list of its angles admits of an easy construction of its surface projection. The projection of the macula lutea should be the center of the field of vision.

COMPLETE APHASIA WITH RIGHT HEMIPLEGIA AND HEMIOPIA, AND AGRAPIA: CURE OF THE PARALYSIS AND RETURN OF SPEECH, BUT PERSISTENCE OF THE HEMIOPIA, AGRAPIA, AND WORD-BLINDNESS.—ARNAUD ("Recueil d'ophtalmologie," November, 1883) reports a very interesting case of this kind in a man aged sixty-six. The patient awoke one morning with complete right hemiplegia and entire loss of the power of speech. He seemed to partially understand what was said to him, and answered by signs, but was plunged into a sort of hebetude. After two months the paralysis began to disappear, and, four months later, the patient had recovered entirely the use of his limbs. He was still dumb, and could not perform any manual labor. He remained in this condition for two years and a half, when he suddenly regained his speech, and from this moment he began to lead a new life. He complained that the right half of his visual field had disappeared at the beginning of his trouble, and so remained. Four years after the trouble began, his intellectual faculties were apparently normal, but his writing was

childish, and he did not recognize a single letter. He has never forgotten figures, and can read them and make mental calculations. He recognizes all colors. The ophthalmoscope showed nothing abnormal. From a purely clinical standpoint, and in view of the correlation which has existed between the various symptoms of a cerebral lesion located with some degree of probability, and absolutely compatible with life, the case is of considerable importance; for it produces a strong belief that the motor center for the leg and arm of the right side, the centers for articulate speech, for the memory of words and of names, and finally for vision in the right half of the visual field, are situated close to one another. The case accords perfectly with the theory of the semi-decussation of the optic-nerve fibers in the chiasm.

VISUAL TROUBLES DUE TO THE ABUSE OF TOBACCO.—Galezowski ("Recueil d'ophtalmologie," November, 1883) returns to the charge in a short paper. The nicotine intoxication generally produces no organic alteration in the eye, and the only perceptible ophthalmoscopic sign is a simple paleness of the papilla due to spasm of the blood-vessels. If, however, the disease is prolonged indefinitely, there are produced certain degenerative changes in the optic-nerve fibers, and finally an atrophy of the papilla. The most characteristic signs of nicotine amblyopia are: myosis, diminution of visual acuity, central scotoma sometimes extending far toward the periphery, which may lead to complete blindness, more or less prolonged, chromatic scotoma, chromatic phenomena, and chromopsia.

DIFFERENT VARIETIES OF DETACHMENT OF THE RETINA, AND THEIR TREATMENT.—Galezowski ("Recueil d'ophtalmologie," November, 1883) begins his paper on this subject by asserting that a detachment of the retina can not occur without the liquefying and softening of the vitreous humor, and without the development of a partial, circumscribed, serous choroiditis in the anterior segment of the choroid, and especially in the ciliary circle. These two conditions are met with in myopic eyes much more frequently than in hypermetropic or eumetropic eyes. This fluidity of the vitreous is not usually general, but limited to the infero-external or supero-external sector, or to the external half, or to isolated regions of the vitreous. When the vitreous is fluid, and a vessel ruptures near the surface of the retina, the extravasated blood runs into the vitreous and sinks in clots. A serous effusion from the choroid may infiltrate the retina, lift it up, and cause a sort of retinal suffusion, without there being any detachment, if the vitreous is not fluid; but, as soon as the latter becomes disintegrated, the detachment takes place. A blow on the eye or a lacerated wound of the sclerotic or internal membranes of the eye, with or without the loss of vitreous, may cause an immediate detachment, if the eye is myopic and the vitreous fluid. If, on the contrary, the eye is hypermetropic or emmetropic and the vitreous is not fluid, the detachment of the retina does not occur until several months after the receipt of such an injury, because time is demanded for the softening and disintegration of the vitreous, which oftentimes follows a series of inflammatory attacks in the iris and ciliary region. This change in the uveal tract is not a simple alteration of the epithelium, but a kind of cyclitis or choroido-cyclitis, circumscribed and limited to a segment, a quarter or a half of the uveal tract, which produces grave alterations in the secretory vessels of the eye.

SINUS THROMBOSIS.—Landsberg ("Centralblatt für prakt. Augenheilkunde," November, 1883) reports an interesting case of this nature in a young man of twenty-one. The patient had frequently suffered from epulis. In September, 1873, he had a similar attack, with swelling of the right cheek and upper lip. A few days later the conjunctiva of both eyes became oedematous. On September 10th Landsberg saw him and found him

so affected as scarcely to be understood. He could not stand alone, and could scarcely take a few steps with assistance. The pupils were moderately dilated and very sluggish; the ocular conjunctiva was pale and oedematous; the right was slightly protruded and completely amaurotic, and the left still had perception of light. The ophthalmoscope revealed nothing abnormal in either eye. An incision into both orbits revealed no pus. On the same night the patient became delirious, and died comatose. No autopsy was made, but the rapid course of the process, its extension to the visual centers and almost complete destruction of vision, without the occurrence of any symptoms pointing to an acute intra-cranial lesion, all point to a diagnosis of sinus thrombosis, probably combined with a meningitic exudation.

A CASE OF PERSISTENCE OF THE FETAL VESSELS OF THE VITREOUS.—Hirschberg ("Centralblatt für prakt. Augenheilkunde," November, 1883) reports a very rare case of this kind occurring in a woman sixty years old. In front of the optic disc and the neighboring retina of the right eye was a shallow, cup-like veil, with no perceptible motion; a very delicate vascular network with but little connective tissue, which proceeded by numerous branches from the physiological excavation of the disc. These branches divided very rapidly and formed anastomoses, and ended finally at the edge of the cup in capillary loops. The arteries could not be distinguished from the veins. The outline of the optic disc was very indistinct. The retinal veins were normal in appearance, but there was but one arterial branch, which ran toward the nasal quadrant. Hirschberg regarded the case, not as one of newly developed vessels, or as a detachment of the retina, but as a case of unusual development of the fetal blood-vessels in the vitreous.

ERYTHROPSIA IN APHAKIA.—Benson ("Ophthalmic Review," December, 1883) reviews all the cases hitherto published, and adds some of his own. He criticises Purtscher's views with reference to the visual acuity in these cases. In all the cases recorded by Purtscher the visual acuity was not less during the attack than it was before or after. If torpor for sudden colors were the true cause, one would expect to find the visual acuity diminished in proportion to the illumination lost; and, as compound white under equal illumination is visible at a greater distance than any of its components, were the red vision due to torpor for other colors, the acuity should be proportionately diminished. Moreover, the intensity of the color is against the fatigue theory, for it is hardly to be conceived that the retina would be so totally insensible to the other colors of the spectrum while having a sensibility so intense for red. In blindness from snow or the electric light, where fatigue, or at least over-stimulation, would seem to be the obvious cause, red vision is not produced. Moreover, in aphakial erythropsia, conjunctivitis is never observed.

EXOPTHALMIC GOITRE, WITH CASES.—Russell ("Ophthalmic Review," November and December, 1883) has here published a series of observations on exophthalmic goitre, based upon twenty-three cases. In six cases general nervous derangement was absent or not mentioned, but in fifteen it was of a decided character, and in eight of the fifteen it overshadowed the other symptoms. In one patient passionate irritability, great willfulness, and hysterical outbursts were combined with obstinate sleeplessness. The phenomena presented by the other cases varied somewhat, but were of an urgent character in all; excessive morbid irritability was the most common symptom; general tremor, dislike of strangers, obstinacy, depression and hypochondriasis, and loss of self-control, were all present. In seven cases the disorder was of the same character, but less severe. In six patients emaciation attained a very advanced stage, in some of them with remarkable rapidity. In one case

emaciation made such alarming progress as to reduce the patient almost to a skeleton in the course of six weeks; the appetite was capricious, but the patient did not refuse food; recovery from this state of attenuation, when once it set in, was even more remarkable from its rapidity; and during its progress the patient exhibited an equal degree of obesity with an inordinate appetite. In twelve patients, either no loss of flesh was experienced, or no mention is made of such an occurrence having taken place. No relation appears to have existed between the degree of nervous and nutritive derangement. Among the eight cases of severe neurotic disorder there were but three in which nutrition had been seriously depressed, while in four either nutrition had been unaffected, or no mention is made of any change of this character. The theory which explains the palpitation, the proptosis, and the goitre by disorder or disease of separate centers, is confirmed by the fact, among others, of the marked want of relation to each other which these three classes of symptoms often present. Thus, of twenty-three cases of Graves's disease, goitre was certainly absent or of questionable existence in six; of these six cases palpitation was extreme in four and proptosis existed in a great degree in one, was absent in one, and was moderate in degree in the others. In four cases out of the twenty-three, proptosis was absent or its presence was not certain. In one of these four cases goitre was also absent, in three it was of large size; in three of the four cases palpitation was severe, in one it was of moderate character. The heart symptoms, specially caused by deranged action, were present in various degrees in all the twenty-three cases. There are also great differences in the order with which the three symptoms of palpitation, proptosis, and goitre make their appearance. In one of the four cases previously alluded to, in which there was no evidence of proptosis, lachrymation was present. In three other cases the eye symptoms were chiefly, if not entirely, limited to an abnormal widening of the palpebral aperture; in two of these the heart symptoms were severe, in one the goitre was large. As regards treatment, Russell has gained the best results by means of iron, strychnine, and cod-liver oil. This tonic treatment may be materially assisted in producing a good effect by a rigidly enforced quietude and by careful nursing.

THE TREATMENT OF "KÉRATITE EN BANDELETTE," OR FASCICULAR KERATITIS.—Prouff ("Revue clinique d'oculistique," January, 1883) gives the following signs of fascicular keratitis, or "kératite en bandelette": 1. Its starting-point near the periphery of the cornea. 2. Its progress in a straight line toward the center of the cornea by means of a slow and continuous ulceration. 3. The development of parallel vessels along the gray basis of the ulceration. 4. Uniformity in breadth of the little band throughout its entire extent. He recommends the following method of treatment: Seize the ocular conjunctiva by a pair of forceps close to the base of the vascular band and lift it away from the eyeball, and then cut this off by a single stroke of the scissors, including in the section, if possible, episcleral tissue and conjunctival limbus. The nutrient vessels are thus divided, and the amelioration of this very chronic form of keratitis is almost immediate.

CLINICAL STUDY OF PRIMARY TUBERCULOSIS OF THE UVEAL TRACT.—Eperon, in this paper ("Archives d'ophtalmologie," Nov.-Dec., 1883), has taken his material for investigation from the clinic of Landolt. His observation was confined to those cases in which the uveal tract was primarily and exclusively the seat of a tuberculous infiltration, usually of slow progress. In one case the tuberculous infiltration was confined to the anterior part of the uveal tract, and at first so deep in the tissues as to be inaccessible to direct examination. It developed rapidly, however, and within a month had caused such grave altera-

tions in the eye as to necessitate its enucleation. There was, however, no other tuberculous point of infiltration in any other part of the body, and the patient was cured by the enucleation of the eye. In a second case the disease was relatively benign in character. In cases of this kind hitherto reported, the diagnosis of tuberculous irido-cyclitis has been rendered easy by the presence of other symptoms—such as ganglionic enlargement, catarrh of the apices of the lungs, tubercular ulcers, infiltrated iris, etc. The ophthalmoscope is not of much assistance, because the infiltration is in front of the ora serrata. Eperon thinks that, when tubercles are easily distinguished in the posterior part of the eyeball, the case is not one of localized ocular tuberculosis, but must be regarded as a prodromal manifestation of a tubercular meningitis or of a generalized miliary tuberculosis. Eperon also thinks that the tubercular virus generally reaches the uveal tract by the anterior lymphatic channels of the eye, and that the aqueous humor is its immediate reservoir. He recommends the early enucleation of the eye as the only remedy in the ocular tuberculosis of infancy and childhood. On the contrary, in the chronic ocular tuberculosis of youths and adults, he thinks we are authorized in trying tonic medication with appropriate hygiene. Operative treatment, in the form of iridectomy, has given a certain amount of success, which, if not permanent, has been tolerably lasting.

PERSISTENCE OF THE HYALOID ARTERY AND PUPILLARY MEMBRANE, DETERMINING INTRA-OCULAR CHANGES WHICH SIMULATED A NEOPLASTIC GROWTH.—Vassaux's paper ("Archives d'ophtalmologie," Nov.-Dec., 1883) is very interesting. The case occurred in a male child fifty-four days old, which had been examined clinically with very great care, and the presence of an intra-ocular tumor diagnosed. The eyeball was enucleated and submitted to a very careful and extended microscopic examination, and no gliomatous tissue was found. Certain plastic changes in the vitreous, together with a persistent hyaloid artery and pupillary membrane, had produced an appearance which clinically resembled strongly that of glioma. Vassaux's paper concludes as follows: 1. The so-called signs or symptoms of Beer, Mauthner, Siehel, and Brière are not pathognomonic of intra-ocular cancer. 2. The persistence of the hyaloid artery with organization of its anterior extremity may clinically simulate this disease. 3. The organization of the anterior extremity of this artery causes complete inversion backward of the ciliary processes, rupture of the zonule, and luxation forward of the crystalline lens. 4. The persistence of the hyaloid artery and pupillary membrane causes the following changes in the lens: anterior and posterior cortical cataract, or liquefaction, swelling and rupture of the lens. 5. The hyaloid canal should not be considered as formed by the hyaloid membrane, but by the lymphatic sheath which surrounds the hyaloid artery.

HEMERALOPIA DEPENDENT ON AN ATYPICAL FORM OF RETINITIS.—Dor ("Archives d'ophtalmologie," Nov.-Dec., 1883) has an interesting paper upon permanent non-essential hemeralopia occurring in retinitis pigmentosa or in those forms of latent retinitis in which the ophthalmoscope reveals no lesion other than a slight diminution in the caliber of the vessels. There is a very considerable narrowing of the visual field. In one case examined by Dor the retina presented a whitish-gray reflex as far forward as the equatorial region, where the red reflex remained. The line of demarkation between the two colors was by no means well-marked, and was very irregular. The vessels were normal in size and color, as was also the disc. There was no differentiation of the macula. In this case the pathological change was posterior to the bacillar layer, as there was very little disturbance of vision and no scotoma, and the lesion was probably in the pigment layer.

(To be continued.)

Miscellany.

THERAPEUTICAL NOTES.—*Carbolic Acid in Diphtheria.*—In the January number of the "Therapeutic Gazette" Dr. F. C. Herr, of Philadelphia, speaks highly of the corrosive-sublimate treatment of diphtheria by a method which, he says, was introduced by Dr. Linn, of Pennsylvania. In the case of a child under ten years of age the drug is given in doses of from one sixteenth to one twelfth of a grain every two to four hours. The administration of the remedy is continued until the exudation has disappeared, unless salivation takes place—an occurrence which the author thinks is not likely to be met with so long as the system is under the influence of the diphtheritic poison. However, the use of the mercurial should be discontinued if improvement is not shown after a few doses have been given.

Kalrine.—An editorial article in the "British Medical Journal" for January 12th gives a short sketch of the chemistry and the physiological action of this alkaloid, together with an account of the results obtained with it by a number of clinical observers. About the same ground has already been covered in this journal, and it is only necessary to add that the objections to the drug as an antipyretic are shown to be very considerable. It is expensive, disagreeable to the taste, and decidedly transitory in its action—to say nothing of the utter failure of some observers to confirm the high estimate of its powers formed by Filehne. Our contemporary thinks it will have its day, and then fall into disuse.

The Antagonism of Alcohol and Strychnine.—According to the "Lancet," a recent discussion in a French temperance society tended to bring out the fact that the antagonism between these two agents does not extend to any mitigation of the ulterior effects of alcohol on the system by giving strychnine at the same time. It was allowed, nevertheless, that a person who had taken alcohol in quantity sufficient to produce drunkenness under ordinary circumstances would not show its effects if he were under the influence of strychnine also.

Pyrologeneous Acid in the Treatment of Ringworm.—At a recent meeting of the French Academy of Medicine, M. Besnier ("Gazette hebdomadaire de médecine et de chirurgie," January 11, 1884) reported upon a memoir on the treatment of the tinea, by Dr. Cramoisy, of Paris. Alluding to the necessity of reaching the depths of the hair follicles in cases of affection of hairy parts, M. Cramoisy expressed the opinion that epilation was usually of little avail, in consequence of the difficulty of removing the hairs entire, rendered brittle as they were by the action of the parasite. He would therefore discard the practice, and seek for some penetrating agent; and this, he thought, was to be found in pyrologeneous acid. He used a solution of one part of red oxide of mercury, two parts of salicylic acid, and one thousand parts of pyrologeneous acid. M. Besnier remarked that pyrologeneous acid was not inferior to a number of the applications in common use for tinea of the varieties that usually did well, but that he could not admit that it had any superiority over the others. As for favus and the intractable forms of trichophytosis, no application could take the place of a thorough mechanical removal of the parasite and the exfoliation of those layers of the epidermis in which it was lodged. He therefore saw nothing special to be gained by the use of pyrologeneous acid, and, moreover, it was necessary to inculcate caution in its use; it should not be applied to large surfaces at a time, as it might produce denuded spots that would be susceptible of inoculation.

THE BOARD OF HEALTH AND ADULTERATED TEA.—Judge O'Gorman, of the Superior Court of this city, rules very technically on the powers of the Board of Health to prevent by injunction the sale of adulterated articles of food. In the case in question, a cargo of Pingsuey teas was under examination, and the judge found as a fact that they were "found to be colored green heavily by means of mineral matter composed of Prussian blue. They contain soapstone ground to powder, clay called terra alba, or gypsum, sand or gravel and ash, and, in many instances, 'he tea,' which is a substance made to imitate tea, and composed of unround, exhausted, and rotten leaves, filth, the sweepings of factory floors, and rubbish of all kinds, cemented together with starch or other adhesive substance, and made into particles resembling tea." Notwithstanding these facts, the judge decided that: "The claim that

these teas were wholesome and deleterious, because composed of foreign matter liable to contain poisonous germs impossible of detection, was not followed by proof that the adulterations were positively and actively poisonous or detrimental to health. Besides, there is no evidence that the quantity of these foreign substances likely to be consumed in the ordinary mode of using tea would be enough to injure health, or that some of them would be taken into the stomach at all—sand or gravel, for instance, which would be likely to fall to the bottom of the cup—and it was somewhat remarkable that, notwithstanding the fact that the quantity of these Pingsuey teas recently imported amounts to nearly one third of all the teas which arrive in this market, there was no evidence to show that any one had suffered in health from drinking them."

Judge O'Gorman does not hold, however, that the public are absolutely without remedy in the matter, although he declines to issue an injunction, but says that there are other legal means by which the sale of food or drink proved to be injurious to the public health can be punished and prevented.

DIASTASIS AT THE ELBOW IN CHILDREN.—In the course of a recent clinical lecture ("Med. Times and Gaz."), Mr. Jonathan Hutchinson remarks that partial separations of the epiphysis are very much more common than complete ones, and much more difficult to diagnose. Any part of the epiphysis may give way, the central part or either of the condyles. In some cases, in addition to the separation, at some part of the epiphyseal area there is an oblique fracture of the shaft. We must be prepared for all sorts of complications. If there is any obscurity about a case, we may be sure that it is one of injury to the epiphysis—an uncomplicated dislocation is easy to recognize, easy to reduce, and not very difficult to keep in place. We all know that in adults dislocations at the elbow get well readily after reduction, and without any stiffness. In children how different is the prospect! In them the elbow nearly always remains more or less restricted in its movements. The cause of this is not alone the persisting malposition of the fragments, although that accounts for much; it is to be explained in large part by the fact that in such injuries the periosteum is always much stripped up, which leads to extensive deposit of new bone. After a while, however, in these young subjects, the bone, although much altered in form at first, becomes remodeled, and, in the course of a few years, almost perfect restoration of movement may be expected. Not infrequently, however, the growth of the bone is arrested to a certain extent, and, if the separation of the epiphysis has been only partial, it may chance that permanent and very peculiar alterations may result. It will often puzzle the best anatomist to give anything like a confident interpretation of the case; over and over again he has known most remarkable differences of opinion between those who were well entitled to give them, and more than once it has been his lot to save a child from an attempt at the forcible reduction of what was supposed to be an old dislocation, by persuading the surgeon that the case was really one of separation of the epiphysis.

In conclusion, he gives the following practical rules: Never forget the epiphyses—that they are the weakest part of the bone. Always suspect that the injury is complicated—in part a dislocation at the joint, and in part a displacement at the epiphyseal junction. Remember that simple and complete detachments of the lower epiphysis of the humerus are more common than simple dislocations of both bones backward. Never give a diagnosis, if the case is the least puzzling, without putting the child under ether and making a careful examination. Never be content unless you can easily put the limb up with the elbow well bent. Be very careful to give a guarded opinion to the parents, knowing that in nine out of ten simple dislocations there is damage either to the coronoid process or to the lower end of the humerus, and that some impediment to free motion is almost sure to result for a time.

THE PROFESSION IN GREAT BRITAIN.—According to an analysis of the new issue of the British "Medical Directory" given in the "Medical Times and Gazette," the whole number of practitioners is 26,038: 4,417 in London, 11,776 in the provincial list, 2,206 in Scotland, 2,430 in Ireland, 1,717 resident abroad, and 2,493 in the army, the navy, the Indian Medical Service, and the mercantile marine.

Lectures and Addresses.

THE CARTWRIGHT LECTURES

ON

METHODS OF STUDYING THE BRAIN,

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 6, 1884.

By BURT G. WILDER, M. D.,

PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

LECTURE I.

Limitations of the Subject to Macroscopic Encephalic Morphology.—Methods of Regarding the Brain based upon its Condition in Embryos and in Amphibia.

MR. PRESIDENT, LADIES, AND GENTLEMEN: In fulfilling my acceptance of your invitation to deliver the lectures upon the Cartwright Foundation this year, I desire to express my wish that such testamentary provisions may be multiplied, my pleasure in addressing an Alumni Association which includes so many of my former pupils, and the sense of mingled eagerness and hesitation with which I speak upon the brain in a city which has a Neurological Society and is the meeting-place of the National Association.

The title, as announced, "Methods of Studying the Brain," is so brief and comprehensive as to be misleading. To avoid, therefore, all occasion for misconception or disappointment, and especially to forestall the criticism which might be brought justly against a proposition to describe fully in three lectures all methods of studying the brains of all vertebrates, I hasten to state that the facts and considerations to be laid before you are exclusively *morphological*; that comparative anatomy and general zoology and embryology have place only in so far as they elucidate human anatomy; and that histology, physiology, pathology, and psychology are omitted altogether.

These latter methods of regarding the brain, it is true, immediately subserve the ultimate purpose of the physician to recognize the nature and causes of encephalic disorder, to anticipate results, and to avert such as may be undesired; but surely it is equally true that microscopical, experimental, pathological, and psychological observations and discussions are more reliable and fruitful when based upon that living knowledge of the visible constitution of the organ concerned which is to be gained only through prolonged personal and familiar acquaintance.*

Leaving, then, to others the honor of discussing the more advanced and difficult topics named above, be mine the humbler task of attempting the exposition of some primary facts, methods, and ideas which may help to make wider, deeper, and more substantial the foundations of neurological science.

This limitation of the subject requires an extension of the title, which now may read as follows:

Outlines and Illustrations of some Methods of Regarding, Obtaining, Preserving, Examining, Figuring, and Describing the Brains of certain Amphibia and Mammalia, which have proved useful in the Anatomical Laboratory of Cornell University, which appear to be unfamiliar to many physicians, and which it is hoped may aid them in acquiring, retaining, and imparting clear, real, and accurate knowledge of the Normal, Macroscopic Structure of the Human Brain.

Mention is made of the successful employment of these methods in the Anatomical Laboratory of Cornell University for two reasons:

First, In acknowledgment of my obligations to my colleagues* and present and former students for suggestions and assistance, and to the President and Trustees of the University for the liberality which has enabled me to obtain the material, preserve the specimens, and perform the experiments through which the results to be described have been attained.

Second, If the fact that these methods have been tested for periods ranging from one to twelve years, in work and instruction in a laboratory where most of the students are preparing for a medical course, be taken as experimental evidence of their worth, then the time which otherwise I might feel called upon to spend in argument may be better employed in illustration.

The methods above indicated fall naturally into three categories, *mental*, *manual*, and *verbal*, involving, respectively, the Recognition of Ideas, the Performance of Manipulations, and the Employment of Terms. This evening I shall offer some general propositions and figures which, in a somewhat extended experience, I have found to facilitate the comprehension of the brain as a whole. On Monday I shall describe certain ways and means of normal encephalotomy. At the closing lecture, in illustration of the results of these methods, I shall ask your attention to features of the brain which are not infrequently overlooked or misunderstood; and finally submit to you some considera-

* Most of the figures are based upon photographs taken by my colleague, Professor S. H. Gage, whose original and ingenious method of using a camera capable of being brought into the vertical position enabled us to obtain pictures of delicate embryos and brains which could hardly have been taken in the ordinary way; some, indeed, were photographed in alcohol, and the *Necturus* shown in Fig. 10 was alive in the water. The drawings have been made by my colleague, Professor E. C. Cleaves, and by Mrs. Gage (whom, like her husband, I am proud to claim as a former student). Aside from their artistic merit, the extreme accuracy of the figures is largely due to the intelligent and painstaking care with which the specimens have been studied in connection with the photographs. To Professor Gage and to Mr. F. L. Kilborne (a former student and now Anatomical Preparator to the University) are also due my thanks for their cordial and skillful assistance, and especially for their aid, often at considerable personal inconvenience, in elaborating and applying the methods of injecting the encephalic vessels and cavities with alcohol. Finally, the plan of pasting the printed names, etc., upon drawings to be reproduced by any of the photo-engraving processes was first employed, so far as I know, in Professor Gage's paper (10).

* "Personal familiarity alone makes knowledge alive."—PHILIP GILBERT HAMERTON.

tions respecting the employment of certain terms of description and designation which are not in common use.*

Consider a human brain. Variouslv viewed, it consists of two, four, six, or more than one hundred parts visible to the unaided eye. A congeries of comparatively simple cells and fibers, yet in action how unlike ligament and connective tissue. Soft, yet molding the skull upon itself. Confined within the head, yet well-nigh omniscient and omnipotent throughout the body. At once the ruler and the servant of all other organs. A mass of matter, yet ministering directly to mind. Who can fitly describe it? Who can hope to comprehend it? No wonder that so few truly wise and candid men pretend to really understand the brain. No wonder that a most accomplished neurologist, at the threshold of a work which I hope may be soon completed, used the following words:

"The cerebro-spinal axis of the adult presents us with such a maze of ganglia, such complicated topographical relations, and such a bewildering labyrinth of unilateral and commissural associating strands, and of direct as well as decussated and interrupted projecting tracts, that not only the student of general medicine, but even many of those who devote their attention to neurology, abandon the task of obtaining more than a knowledge of the cerebral outline as hopeless."—SPITZKA, 6, 2†

Before suggesting the means by which the hopelessness of this task may be diminished, permit me to comment briefly upon some methods of regarding the brain which, so far as I can judge from standard text-books and other sources of information, are not altogether unknown at the average English and American medical college:

1. The brain is regarded as a fibro-cellular mass, penetrated here and there by inconsiderable cavities.

2. Now that these cavities are no longer supposed to be the "reservoirs of animal spirits," or the "receptacles of the excrements which are separated in the nourishment of the organ," all use and significance seems to be denied them.

3. Little attention is paid to the membranes which line these cavities and invest the entire organ.

4. For lack of a clear recognition of the nature of the cavities, there is commonly enumerated therewith a space between two apposed ectal surfaces, the so-called "fifth ventricle," which forms no part of the series, either actually or ideally.

5. On account of its slenderness in man and the higher mammals, one of the primary divisions of the cavity is described as a mere passage of communication, and a like rank is assigned to a division of which the cerebral hemispheres themselves are only diverticula.

6. The fascinations of microscopical technique, the exclusion of the brain from ordinary surgical interference, the difficulty of obtaining the organ in a condition suitable for

* That the use of these unfamiliar terms earlier in the course may cause the least possible embarrassment, the liberality of the lecture committee enables me to place in your hands a sheet on which are printed the technical terms employed in the lectures, together with their more common technical and English equivalents.

† The list of works and papers referred to in these lectures will be appended to the last. In most cases the titles may be found in the bibliographical portion of Wilder and Gage's "Anatomical Technology as applied to the Domestic Cat," pp. 538-553.

dissection, and, finally, the not unnatural tendency of writers and teachers to ignore the necessity for more information than they themselves possess, have led to an undue curtailment of the time given to the gross anatomy of the brain. Is it indeed beyond the range of possibility that a student should be permitted to imagine himself possessed of some knowledge of encephalic anatomy because he can discriminate between *corpus callosum* and *corpus striatum*, or between optic lobe and optic thalamus; or even when he can merely repeat a string of sonorous names, notwithstanding, like the "peripatetic professors of phrenology" mentioned by Ecker, he has "never seen a brain"—seen it, that is, in the sense of having personally and thoroughly dissected it in a fresh or well-preserved condition?

7. The more obvious features of the larger masses are described and figured in detail, while certain lesser points are inadequately discussed or ignored altogether.

8. The morphological significance of some of these slighter features is so little appreciated that the description of an orifice in the "*lamina cinerea*," or the representation of the "third ventricle" without a roof, excites no more surprise than would the enumeration of a larger or smaller number of foramina in the "anterior perforated space."

9. Usually the adult human brain is the first and only object of examination, and is taken as the standard of comparison; if animal brains are studied at all, they are often taken as they come, or as anatomical rarities, not selected in accordance with a principle which might indicate the probable degree of their usefulness.

10. The development of the brain is treated only as a division of embryology, and as such is apt to be overlooked until after the time when it might be most useful in aiding the comprehension of the organ.

11. Most anthropotomical accounts of the development of the brain are well-nigh unintelligible to any but the learned anatomist by reason of their brevity, the introduction of elaborate figures, the slight use of diagrams, the attempt to describe or represent at once all the kinds of changes which affect all parts of the organ, and, finally, by the employment of terms differing, in character or at least in form, from those which occur in the account of the adult brain.

12. A few parts have been named from real or fancied resemblances to other portions of the body or to various objects, but the organ as a whole has been treated as if beyond the pale of analogy and literally incomparable.

13. The visible parts, nearly two hundred in number, are mentioned in descriptive anatomy only in their topographical sequence, and the student is expected to master the details presented by the base of the organ, including the nerve-roots, or on a mesal hemisection, or on transections at various levels, with little or no intimation that the parts thus exposed together belong to quite different divisions.

14. The brain has been variously and incongruously subdivided into two, three, or more parts, with apparently no reference to any underlying plan of organization.

15. With some other complex organs, the effort has been made, more or less successfully, to reduce them to their *simplest terms*; to recognize in each a structural unit which is reproduced with variation throughout the whole. The

liver, for example, is a mass of essentially similar lobules, and the lungs consist of innumerable thin-walled sacs, each surrounded by a capillary network.

16. As to the brain, histologically it is said to consist of cells and fibers, and physiologically of ganglia and nerves, or centers and conductors, or "stations" and "projection systems," but the conception of a *macroscopic encephalic unit* seems not to have been commonly entertained. Moreover, although a segmental constitution of the brain has been more or less distinctly outlined in special papers and in the embryological portions of anatomical compendiums, the encephalic masses have been discussed to the nearly complete exclusion of the cavities.

17. The chief obstacle to the early and clear recognition of the simple character of the encephalic unit has been the enormous development of the *cerebral hemispheres* in man and the higher mammals, and the relative insignificance of the mesal part by which they are connected. Hence has arisen the idea of *encephalic duplicity*—an idea which is supported by the pairs of lateral masses called *thalami*, by the pairs of lateral eminences called *lobi optici*, and especially by the peculiar physiological relations of the two halves of the entire brain with the right and left sides of the body. Thus has it come about, paradoxical as it sounds, that the hindrance to the progress of the philosophical anatomy of the brain has been occasioned mainly by the peculiarities of the very region through which alone philosophy has arisen.

FIG. 1.—RIGHT PROFILE OF A HUMAN EMBRYO (accession No. 274) $\times 6$. Drawn by Professor Cleaves. The dotted line indicates, very nearly, the outline before the dissection by which were exposed the *coelia* and most of the *Canalis centralis*. For a short distance just caudal of the meten, however, the dotted line should coincide with the general outline, as shown in Fig. 2.

The methods of regarding the brain which have been employed in research and instruction in the anatomical laboratory and lecture-room of Cornell University during the last seven years have been evolved from the study of

the organ chiefly as it exists in Embryos, in the frog and *Necturus*, and in the domestic cat.

Whether the naturally deplored difficulty of procuring fresh, adult, human brains has, in our case, proved to be a not altogether unmixed evil, it is not perhaps worth while to inquire. It is certain, however, that the comparative inaccessibility, until recently, of special neurological literature, has had the undesirable effect of deferring my acquaintance with the anticipation of some of these methods by other workers in the same field. On the present occasion it would be impossible to specify in detail the obligations under which otherwise I might have been to Balfour, Hadlich, Mihalkovics, Spitzka, von Baer, Wernicke, and others, but it seems proper to state that, for the views to be submitted in the present lecture, I have to acknowledge indebtedness to only two sources: The description and diagrams of the typical brain in Huxley's "Anatomy of Vertebrated Animals," and the tabular arrangement of the encephalic names in the eighth edition of "Quain's Anatomy."

As examples of the material on which the methods to be outlined are based, I submit specimens, photographs,

FIG. 2.—DORSAL ASPECT OF THE HUMAN EMBRYO SHOWN IN FIG. 1; $\times 6$. Drawn by Professor Cleaves. The *coelia* have been exposed, together with the *Canalis centralis*, except at two points. At most parts no attempt has been made to distinguish between the thin body wall and the encephalic parietes.

and drawings of the brains of a human embryo eighteen millimetres long,* and of an adult *Necturus*, frog,† and cat.

* The embryo has a distinct tail. Its limbs are flipper-like, the indications of digital differentiation being more distinct on the manus than on the pes. The outline of the heart is dimly seen. All the parts of the face are recognizable, but the eyeballs are uncovered and the ears and nostrils are pits. The head is enormous, constituting about half of the whole.

† The figure of the frog's will be given farther on.

The following points are illustrated thereby:

1. The persistence of the Canalis centralis of the myelon

FIG. 3.—VENTRAL ASPECT OF THE HUMAN EMBRYO SHOWN IN FIG. 1 AND FIG. 2; × 6. Drawn by Professor Cleaves. The proœcia, the diacœlia, and part of the mesocœlia are seen. Except at the meson and on the sides, where the hemispheres join the diacœlian walls, no attempt has been made to distinguish the body wall from the proper cœlian parietes.

(which remains open in the adult cat and most other mammals, but is usually obliterated in the human adult), even into the caudal termination.

FIG. 4.—THE ENTIRE SERIES OF CœLIA OF THE HUMAN EMBRYO SHOWN IN FIG. 1, FIG. 2, AND FIG. 3; × 6. Drawn by Professor Cleaves. The cœlia, which, on account of the cranial flexure, really appear on the ventral aspect of the embryo are supposed to be brought into the same plane with the dorsal series, so as to be comparable with those of *Necturus*.

2. The continuation of the Canalis centralis into the head as a series of mesal cavities (cœlia, or "ventricles"), more or less distinctly defined.

3. The corresponding segmentation of the walls of these cavities.

4. The thinness of the parietes, and the corresponding extent of the cavities in the embryo and *Necturus*.

5. The slenderness of the intermediate cavity (mesocœlia) in the cat, its simplicity in the embryo and *Necturus*, and its subdivision in the frog into one mesal and two lateral cavities.

6. The lateral extension of the most cephalic division (proœcia), slight in the embryo, greater in *Necturus*, and very extensive and irregular in the cat.

7. The corresponding, relative insignificance of the mesal portion (aula) of this cavity in the cat, and its greater size in the others.

8. The great extent of the most caudal cavity (metacœlia) in the embryo and *Necturus*, and the narrowness of the band representing the cerebellum.

9. The continuity of the parietes in the embryo and *Necturus*.

10. The apparent interruption of the proœcian walls in the cat for the admission of a plexus, but their real continuity by reason of the reflection of the endyma thereon.

11. The extension of the entire brain upon the same plane with *Necturus*, and the marked flexure in the embryo, by which the mesocœlia becomes cephalic in position, the proœcia and diacœlia ventral, while the metacœlia and epicœlia remain dorsal.

FIG. 5.—DORSAL ASPECT OF THE BRAIN OF *NECTURUS*; × 3. Drawn by Mrs. Gage. All the segments are visible, but the narrow cerebellum is mostly hidden by the extensive metaplexus. There is no evidence of a "foramen of Magendie," either in the appearances presented, or upon inflation, or injection of the cœlia with alcohol.

12. It should be stated that the non-appearance of the Lobi olfactorii in the cat is due to their removal with the other parts at the base of the brain; in the embryo they

may not have been formed. Apparently there are no plexuses in the embryo at this stage; in *Necturus* they are very

FIG. 6.—DORSAL EXPOSURE OF THE CELLS OF *NECTURUS*; $\times 3$. Drawn by Mrs. Gage. The aula and porta are very extensive, and the lateral portions of the procoelia relatively small.

extensive, but were removed for the sake of exposing the outlines more distinctly.

The most general statement of the methods recommended may be made in the form of six propositions:

A. The comprehension of the macroscopic morphology of the brain involves the removal of difficulties varying in kind and degree. These several categories of difficulties should be attacked separately, and in the order of (1) their fundamental importance and (2) their simplicity.

B. The arrangements of the solid parts of the brain are more readily perceived and more easily remembered after the relations of the cavities are fully understood.

C. An adequate idea of the circumscription of the cavities involves a distinct recognition of their lining and of the investment of the whole brain.

D. Even when the adult human brain is the ultimate object of inquiry, its detailed study should be preceded, rather than followed, by the examination of embryonic and certain animal brains.

E. The arrangements of the encephalic parietes are more readily appreciated if we disregard altogether their organic composition and their direct subservience to mental operations, and view the brain primarily as we might any artificial structure, like a house or a piece of furniture of homogeneous material.

F. In the attempt to comprehend or explain the various complications of encephalic architecture, by the comparison of the brains of different animals, or at various stages of individual development (ontogenesis), or as hypothetically evolved, in geological time (phylogenesis), diagrams should largely take the place of descriptions, even although we

may be compelled, provisionally, to assume a knowledge of intermediate steps which may not have been actually observed.

In the following amplification of these general propositions there are, I think, some statements and suggestions which have not as yet become part of the common stock of medical knowledge, and may therefore be appropriately discussed in a course like this. But the exigencies of logical and connected sequence may cause the introduction of some matters which, perhaps, appertain more strictly to elementary instruction. In a great medical center like this, however, a very large number of physicians are, or probably will be, the preceptors of one or more students. As such, even if the suggestion of a personal receptivity of additional information respecting the brain may be altogether out of place, some of them may gather hints which will enable them to co-operate more efficiently with the instruction of the schools.

A primary wish of the intelligent student of a complex structure is for a definition which is at once correct, clear, and comprehensive—the concise expression of the most general conception of its constant and essential characters.

Excluding the lowest three genera—*Branchiostoma* or amphioxus, *Myxine*, and *Bdellostoma*—the most general macroscopic morphological features of the vertebrate brain are as follows:

1. It is *elongated*. 2. It is *hollow*. 3. It is *constricted* at several points. 4. It is the cephalic continuation of the myelon.

Combining these, we have the following macro-morphological definition of the brain: A Segmented Entocranial Tube.

The recognition of the segmental constitution of the brain does not involve either of the following matters: (A) The precise number of segments; (B) The identity of their development; (C) The physiological identity of an entire segment; (D) The absolute physiological distinction between two segments.

The cavity of each segment is primarily and essentially a short, subspherical cylinder, open at either end, excepting the cephalic end of the last.

The primary segmental cavities constitute a *single mesal series*, but from several of them are produced *lateral diverticula*.*

These diverticula may be formed, by budding, at a very early period, as, e.g., the *optic vesicles*; or later, as is probably the case with the so-called *optic ventricles* of frogs and birds. The lumina may persist through life, as in the latter instance; or be obliterated, as in the former, where they form the *optic tracts*. In both cases they are comparatively simple in form, and in some animals (*Necturus*, *Petromyzon*, etc.) this is true also with the most cephalic diverticula, which become the cerebral hemispheres and *Lobi olfactorii*. In man, however, and the mammals generally, the cerebral diverticula become disproportionately large; their cavities, the so-called "lateral ventricles," are very irregular in form, and

* In this, and in a few other points, there will be found indications of a change in my views since the preparation of the chapter on the brain in Wilder and Gage's "Anatomical Technology."

so much more extensive than the primitive mesal cavity from which they sprung, that the latter is sometimes overlooked altogether.

FIG. 7.—VENTRAL EXPOSURE OF THE CELLS OF THE CAT: $\times 2$. Drawn by Mrs. Gage. The cells were injected with alcohol to, and perhaps slightly beyond, their natural size. The ventral portion of the brain was removed at the level of the porta ("foramen Monroi") and mesocle (aqueo-lacune Sylvii). The sides of the cells are also removed to a certain extent, so as to show their continuity and the various nature of the roof. On the left side the præcornu and medicornu are shown to be connected by the removal of the intervening portion of the hemisphere. On the right side is shown the entrance of the plexus (prpx.) into the medicornu through the rima, but it is covered by the reflected endyma. The mediodiverticulum was removed altogether. The crista is shown as a mesal elevation at the cephalic side of the aula.

But it must be borne in mind that in frogs and birds the lateral masses and cavities constituting the optic lobes are also both large and complicated. Indeed, prejudice aside, they might well be designated as "hemispheres" and "cornua." Whatever may be the actual directions of these diverticula, all should be reduced to one normal position, extending laterad at right angles with the mesal line representing the primary cœlian series.

If these considerations are sound, it is obviously unnatural to define the brain as a bifurcated or Y-shaped or T-shaped tube. Or, if the lateral prolongations at the cephalic end of the organ are indicated, then the equally real and sometimes even more extensive prolongations at other points must also be represented by lines crossing the main cœlian axis.

The case is strictly analogous to that of the limbs. Whatever be the *natural attitude* of the arms and legs in different animals, it is now almost universally conceded that their *normal position* is at right angles with the body axis.

Practically, the cerebral hemispheres, like the legs of a man, constitute a part of the *length* of the brain; morphologically, however, they are elements of its transverse dimension—the *width*—and are to be paralleled with the lateral diverticula of the optic lobes, just as the legs are to be brought into line with the outstretched arms.

FIG. 8.—SCHEMATIC TRANSECTIONS OF THREE GENERAL CONDITIONS OF THE ENCEPHALIC UNIT. A, the primary, simple, thin-walled cavity. B, the secondary stage, in which the walls are thicker, and there are three connected cavities—one mesal and two lateral. C, the permanent condition in the mammals, the cavities, especially the mesal, dwarfed by the development of the walls of the lateral ones.

The simplest representation of the encephalic unit is as a *single* thin-walled cavity, as it is in the early embryonic stages. Secondly, and in accordance with some facts

FIG. 9.—SCHEMATIC DIAGRAM OF THE DORSUM OF A BRAIN in which two segments are simple, while each of the others presents lateral diverticula, representing, respectively, the cerebral hemispheres, the optic vesicles, and the lateral "optic ventricles."

of comparative anatomy, but still from the purely macro-morphological standpoint, there are *three* communicating cavities—one mesal and two lateral. Finally, the cavities are practically obliterated, and, from the histologico-physiological standpoint, we have *two* lateral masses conjoined by transverse commissures. In more concise verbal form, the embryological idea of the brain is *unity*; the morphological idea is *triplicity*, while the physiological idea is *duplicity*.

The cavities of normal, adult mammalian brains are comparatively atelic, and hardly more than traces of what existed in their own early stages and presumably in the remote ancestors of mammals, as in the Amphibia of the present day. *Hydrocephalus* is a retention or exaggeration of this normal embryonic condition, and brains thus affected, if properly preserved and examined, may very clearly illustrate the manner of circumscription of the cavities.

In the brain, as in other regions of the body, the teleological importance of a part may be no index of its morphological significance, and may even be inversely thereto.

In addition to the usefulness of a knowledge of the relations of the cavities in facilitating a comprehension of the plan of the brain, their location is very nearly a guide to the distribution of the ganglionic centers and the course of the fibrous conductors and channels of blood-supply. Intrusions of vascular plexuses occur at various points, but the larger vessels rarely invade the cavities. Only in the mammals, and perhaps not in all of them, is the cœlian privacy disturbed by that most unsubstantial union of the two thalami known as the "soft commissure." Moreover, excepting the commissure just named, and the *callosum* and the filmy mesal line of the *fornix*, there are few if any "short

cuts" in the brain. Contiguity is thus no evidence of continuity; the human *pons* and the *chiasma* are almost in contact, but their fibers ascend in distinct segments. The occipital lobes of the cerebrum overlap the cerebellum, yet are but remotely connected therewith. The end of the fimbria passes within three centimetres of the corresponding *albicans*, but the shortest route between them follows the circuitous spiral of the cornu through a distance five times as great. In other words, the encephalic railroads and telegraphs skirt the comparatively insignificant remnants of the once extensive spaces about which they were first established, as if Kansas City and Chicago could communicate only by heading the sources of the Mississippi in respectful commemoration of the vast gulf of which even the "Father of Waters" is only a trace.

After the complete closure of the encephalic region of the embryonic neural canal, the presumption is that the cavity so formed is *completely surrounded*, and that the parietes are continuous. The burden of proof should therefore rest with those who affirm the existence of orifices or other interruptions of this continuity. The alleged "foramina of Magendie" will be referred to later; elsewhere than in the roof of the so-called "fourth ventricle" there is no sufficient evidence of any solution of parietal continuity, and the plexuses which apparently enter the cavities may be shown, readily and without the aid of the microscope, to be related thereto only as the abdominal viscera are related to the cavity of the peritonæum.

Eventually, the study of the cranial nerves may aid in the determination of the number of encephalic segments, but for the present the nerve-roots should be omitted from the primary study of the organ, excepting the olfactory nerves, which are practically lobes, and the optic, the *chiasma* of which forms a prominent topographical landmark.

To become an accomplished embryologist or comparative anatomist demands an amount of time and mental expenditure which rarely can be spared from the sacred duties of medical practice or preparation; perhaps, indeed, will never be so taken by the sincere practitioner even when his patients are only the helpless soldiers or sailors of the United States. But, unless he is so fortunate as to have had a thorough preliminary training in general biology, he should—provided he desires to think and understand as well as to see and know—take early and frequent opportunities of examining the simple brains of Amphibia and lower mammals, and of mammalian embryos.

The animal brains examined by the medical anatomist as an aid to the comprehension of the general arrangement of the organ should be chosen because either (A) they are simpler than the human brain and readily comparable therewith; or (B) they are obtainable promptly and in sufficient numbers; or (C) the animals lie in or near the presumed line of human ancestry.

The resemblance between the brains of early human and shark embryos is really startling, and a fuller knowledge of the brains of *Petromyzon*, *Ceratodus*, *Protopterus*, and *Lepidosiren* will certainly aid in clearing up the relations of the mesal and lateral divisions of the most cephalic segment; but there are obvious practical obstacles to the

general employment of these forms. On the other hand, medical neurologists are sometimes led into an examination of the brains of the Teleostei, partly because they may be had at any time, and partly in accordance with the popular belief that all the organs of all other vertebrates are, of necessity, simpler than those of man. The general question here indicated is too broad for discussion on the present occasion, and I therefore content myself with expressing the doubt which, in common with others, I have been forced to entertain as to whether (A) man is the highest mammal, and (B) the human body is now as perfect, anatomically and physiologically, as it may reasonably be expected to become if the natural laws of the past are to operate likewise in the future.* With regard, however, to the special instance of the teleostean brain, there need be no hesitation in declaring that the commercially "common fish" is so highly specialized as to be zoologically almost a phenomenon. In one single respect may the teleostean brain prove useful to the medical neurologist—namely, in the non-fusion of the optic nerves with each other and with the floor of the so-called "third ventricle," which is thus seen to exist independently of the *chiasma* formed in most other vertebrates; but in all other respects let us be warned by the recollection of the degree in which the progress of human and comparative anatomy was retarded by the powerful and well-meant, though misguided, efforts to base a science of osteology upon that morphological monstrosity, the skull of the cod.

The reptiles are probably, and the birds most certainly, out of the direct line of human descent, and their brains are thus of use only to the advanced neurologist in throwing certain side-lights; for example, in birds the mesocele presents the triple constitution which I hold to be the complete expression of the encephalic unit, and in certain lizards Spitzka has observed the third and intermediate pair of optic lobes which he calls *interoptici*.

As to the mammals, the brains of the lower and smaller forms—opossum, rabbit, etc., with their less developed cerebrum and cerebellum, fornix and callosum—present obvious advantages in the way of simplicity; those of the higher and larger forms—cats, dogs, sheep, monkeys, etc.—are more useful as supplying the material for dissection when human brains can not be had, while those of the pig can be obtained in all stages of development, as has been so well illustrated in the work upon Human Physiology by the distinguished professor from whom many of my hearers have gained their knowledge of that science.

The remaining vertebrate class, the Amphibia, including the frogs, toads, and salamanders, fulfills, as a whole, all four of the conditions named above. The advantages presented by the frog's brain have been admirably described by Wyman,† and may be more categorically stated as follows:

* The physician who has lost a patient in consequence of the lodgment of a grape-seed, or other natural constituent of wholesome food, in the *appendix vermiformis*, may endeavor to reconcile the calamity with popular belief, but will more properly look forward to the period when this worse than "worthless primeval heirloom" will have ceased to be an element of human structure.

1. The various parts, while far from equal in size, differ much less than in the higher Vertebrates.
2. No part is completely hidden by another.
3. All lie in the same plane.
4. The cavities are relatively large.
5. The parietes vary little in thickness.

FIG. 10.—DORSAL ASPECT OF A PARTLY BROWN *NECTURUS LATERALIS*. This salamander, sometimes called *Menoponchilus*, is one of the perennibranchiate urodelaous Amphibia. Having both pairs of limbs, as well as a tail, and ootobranchiae ("external gills"), as well as simple lungs, it is a very comprehensive vertebrate; and, as urged by the writer at the meeting of the Society of Naturalists of the Eastern United States, December 28, 1883, much better adapted than the frog for elementary zoological and morphological study. The extreme coarseness of most of its tissues fits it likewise for histological purposes.

The figure (drawn by Mrs. Gage) is taken, by permission, from Professor S. H. Gage's paper, "Observations on the Fat Cells and Connective-tissue Corpuscles of *Necturus*," Proceedings of the Am. Soc. of Microscopists, iv, 1883.

6. While all the primary components of the brain are present, there are but few special additions or modifications to distract attention from the general plan.

7. There are three "optic ventricles" or divisions of the mesocele—one mesal and two lateral, as in birds.

In view of all these excellences and the very obvious advantages for general dissection afforded by a creature which is readily obtainable and wholly inoffensive, whose tissues are coarse, and whose organs are readily separable, the very skin being, as it were, only "basted on," to criticise the frog as a subject of elementary anatomical study is to deride a laboratory fetic. Nevertheless, for beginners, the frog's brain is objectionable, because (A) the plexuses are almost wholly wanting; (B) in common with the other Anura, there is, in the adult, a close conjunction of the *Lobi olfactorii* which is anomalous and misleading. I say misleading, because it not only puzzles the beginner, but also, inasmuch as the hemispheres remain separate, there is formed a sort of nervous ring; and even the late Jeffries Wyman, who made so few mistakes in observation and interpretation as to merit the title of the anatomical George Washington, compared it with the œsophageal ring of some invertebrates. In view of these considerations, would it not be well to disconnect the olfactory lobes when a frog's brain is first examined, and should not more frequent and systematic use be made of the large salamander *Necturus* (Fig. 10) already mentioned?*

But even the *Necturus* brain has its drawbacks, and it must be admitted that a great desideratum of the teacher and student of encephalic morphology is a brain constructed on the general pattern of that of *Necturus*, but with the firm texture and more distinct cerebellum of the frog, and at least as large as the brain of the giant *Megalobatrachus* of Japan.

(To be concluded.)

THE RECIPROCAL ATTITUDE OF THE MEDICAL PROFESSION AND THE COMMUNITY.

THE ANNIVERSARY ADDRESS BEFORE THE MEDICAL SOCIETY
OF THE STATE OF NEW YORK, AT THE SEVENTY-
EIGHTH ANNUAL MEETING.

Delivered at Albany, February 6, 1884.

By ALEXANDER HUTCHINS, A. M., M. D.,
OF BROOKLYN, N. Y.,
PRESIDENT OF THE SOCIETY.

THERE is a medical science, but if medicine were a science only, there would be fewer medical schools than now exist.

The former part of this proposition has been flatly denied. The impression is prevalent, and the expression of opinion frequent, that while much learning has been amassed in medical research, the results thereof are so unrelated, and the conclusions so untrustworthy as a basis for future observers, that, even conceding that some of its methods are

* When the fishermen find that a "mad-puppy" has a pecuniary value, they soon overcome the superstition that it is venomous. At most seasons of the year *Necturi* may be obtained from Mr. Russell Dee, Harnar, Ohio.

scientific, in the catalogue of the sciences it is to be classed among the empirical, and not in the exact.

The scope of intellectual activity has varied with many epochs and many climes, and the verbal definitions that have marked the limits of one epoch are not applicable to the ranges that have been traversed by thinkers and investigators of later periods. Aristotle, as a naturalist, holds a fixed relation to zoological science; so likewise does Cuvier; but the types of Darwin have disentangled and wrought into new shapes the words that defined the science of the Frenchman and the Greek. The schoolmen of the middle ages found the beginning of things far posterior to the times into which the Egyptologists of to-day have groped, and the forms of speech that outline ethnology in this year of grace would have been cabalistic and meaningless to the thoughtful brows in whose presence men paid homage in the days of Charlemagne. The marble busts in our own Pantheon cause in us obeisance to the venerable and honored men who wrought and healed to the world's great good; but the man of Cos, who framed the oath to which we have all subscribed, would need to learn his alphabet anew were he to attempt the terms that limit the medical science of this later century.

Scholars there have been in all ages, and through each era in the growth of knowledge, as leisure or inclination prompted, the lines have been sharply drawn between those who have wrought into new forms truth that has been revealed and those who have labored in the discovery of truth to which the world had hitherto been a stranger. No comparison can be instituted between Bancroft and Agassiz.

The scope of the sciences has been so enlarged as to affect many and diverse directions of investigation, where the investigation has developed an orderly arrangement of facts and principles; and classified knowledge, in any special line, elevates that knowledge into the rank of the sciences. Still, words have a recognized application, and, although there is a legal science, the Supreme Court is not a scientific body.

Knowledge is so interwoven, one branch with another, that a rich culture in one line of research implies and necessitates extensive knowledge of related studies; and this advance of general knowledge is the result of advance of special inquiry, and stimulates to the greater subdivision of special study. The number of the sciences increases with each intellectual epoch, and the sciences themselves become the subject of grouping. Human anatomy is a science, and, in its orderly classification of structure and relation, was a science long before the dependent science of histology unraveled the closely woven web that held so many mysteries in its fast embrace; before physiological science lifted the veil and disclosed the inevitable necessities of related structure; before chemical science touched with her magic wand the sealed volume where lay inscribed the hidden processes of waste and repair; before pathological science began her study of the myriad variations from the ideal type of structure, and of the utmost bounds where the interrupted harmony of process becomes discord, beyond which is dissolution; before the science of embryology all but touched the

confines where the creative force starts the complex human mechanism in its infinite reproduction; before comparative science demonstrated the unity of animal organism; before biological science grouped all living organization, to make clear the intimate similarity that exists in all structures informed by the element called life.

The results of the world's labor, which have become the foundation of medical learning, are on open pages which all may read. Not with gigantic strides have the distances been traversed, not by herculean labors have the stones been placed, but slowly, patiently, insensibly, have the toiling students of living things observed, recorded, and grouped, one generation after another, names multitudinous and lost to history, till the student, who starts afresh to-day, stands debtor to a scholarly ancestry, as remote as the world's past, connected with a succession of humble ministers on Nature, as remote as the world's end, whose absorbing inspiration is the genius of true scholarship the wide world over—the search for truth and its free gift to mankind.

Though biological research is a new phrase in science, its multimorph processes and the character of its results have been identical, all along the history of the investigation of life, before they were compacted into the more modern classification. Medical science assumed her unique place among the sciences when the facts and phenomena evoked by biological research were made the basis of investigation, whose purpose is to prolong the vital process and arrest the untoward influences that perpetually threaten its extinction. This is her distinctive mission. The facts are not wanting to support the belief that, through the varying civilizations, the protection of communities has been the object of her forethought, and hygienic measures have shaped themselves into laws; yet it has been reserved to the present century to enunciate the problem of how communities are to be protected, and to formulate laws in accord with strictly scientific methods, looking to the prevention of disorder and the prolongation of human life; yet the individual has always been the object of her solicitude, and the record shows how persistently, according to the lights of each era, the precepts of personal hygiene have been inculcated, and how, with each marked acquisition in scientific knowledge, scientific methods have been applied to the preservation of the individual. There is a luminous record of proof to show that the brilliant achievements in principles and detail that have been applied to the recovery from disordered process, have been the rational outcome from an antecedent advance in scientific inquiry, could not have been possible without that knowledge, and have not been merely haphazard and accidental. It is clear, also, that the tremendous strides in scientific knowledge the present century has witnessed, springing from the increased facilities for the diffusion of knowledge and the rapid interchange of thought, have been the impulse to the intelligent and far-reaching and exact methods that have prolonged life and increased the sum of human happiness among the civilized races. The instruments of precision that have contributed so much to exact knowledge of normal structure and activity have been supplemented by instruments of precision that settle the terms of definite prognosis. The appliances for

distortion, the agents that avert the shock of operation, the simplification of treatment through the known sequence of morbid phenomena, the separation of the active principles of remedies, the differentiating selection of therapeutic measures, the discriminating nomenclature, the humane treatment of the insane, and the skilled knowledge that has made possible the bold measures of surgical interference, are results based on scientific research, and but for that would not have been possible as instances of methodical procedure.

Though some names are inseparably connected with the beginning of certain movements that have become classic—as Simpson with chloroform, McDowell with ovariectomy, von Graefe with glaucoma—yet the rule is so invariable that the principles and details which give accuracy to the rectification of morbid process have had for an antecedent precise information of normal activity, derived from so many sources, that priority of claim can rarely be made good. The body of medical science is the slow accretion of the centuries, and the contributions to its learning are too numerous for the historic pen. The results of yesterday are the alphabet of to-day. Dogma is flashing but evanescent. The multitude of observers and the host of journals which give rapid interchange of thought betoken the industry which gives it distinguished place in the procession of research. The unproved is rapidly discarded, the good is improved upon and becomes common property. But seventy-five years have gone since the ovarian cyst was excised by the grave Kentuckian whose honored memory his grateful brethren have perpetuated by the granite obelisk* in the Danville churchyard, and, by a skillful use of exceptional opportunity, the Scottish chieftain is justly credited with having added hundreds of years to woman's life; and not only that, but, wherever this literature has reached, men, whose names can never become historic, are performing this merciful task with assurance and success. But fourteen years have gone by since the turf hid the gifted German† who revolutionized the operation for cataract, but even now the great centers show a phalanx of men whose skill is greater as their experience has increased. By the very genius of the science this history of progress and change must always be repeating. The days rapidly hasten on when the names of McDowell and von Graefe, of Keith and Sims, will be prominent only as land-marks. The apotheosis of the laureate rings aloud of this company as of none other:

"Men, my brothers, men the workers, ever reaping something new,

That which they have done but earnest of the things that they shall do."

Within the past year‡ the father of English Vital Statistics, Dr. William Farr, died at the ripe age of 75 years. In 1837, at the age of 29 years, he published the first English registration report of vital statistics. By a singular coincidence the same month in which his death occurred Mr. N. A. Humphreys read a paper before the Statistical

Society on "The Recent Decline in the English Death-Rate and its effect upon the Duration of Life," wherein he analyzes the Registrar-General's mortality statistics covering 45 years (1838 to 1882). The comparison of Dr. Farr's and Mr. Humphrey's new life tables shows that the mean duration of the life of males has increased from 39.91 years to 41.92; of females from 41.85 years to 45.25 years, or of a generation from 40.86 years to 43.56, showing an increase of 2.70 years, equal to nearly seven per cent. Of course, the importance of this showing is due to the fact that these results are traceable to the enforcement of State medicine and hygiene during this same period.

"Although a large proportion of young people cease to be dependent before twenty, and a large proportion of elderly persons do not become dependent at sixty, we shall not be far wrong in classing the forty years from twenty to sixty as the useful period of man's life. Table IX shows us that of the 2,009 years added to the lives of 1,000 males by the reduction of the death-rate in 1876-1880, no less than 1,407, or seventy per cent., are lived at the useful ages between twenty and sixty. Of the remainder of the increase, 445, or twenty-two per cent., are lived under twenty years, and 157, or one eighth per cent., above sixty years. Thus, of the total increase seventy per cent. is added to the useful, and thirty per cent. to what may be called the dependent-age periods. The increased number of years lived by 1,000 females, according to the rates of mortality that prevailed in 1876-1880, is 3,405. Of these (see Table X), 2,196, or sixty-five per cent., are lived at the useful ages between twenty and sixty; 517, or fifteen per cent., under twenty years of age; and 692, or twenty per cent., over sixty years."

"Looked at from another point of view, there has been an addition of three minutes for men and five minutes for women in England to every hour of their existence, and under her present conditions a country with a population of thirty millions would, at the end of a generation, have two millions more inhabitants than under England's previous conditions.

"Life is not only longer, but active life is begun later, and old age is more robust. We think Mr. Humphrey's analysis of the registration reports will be acknowledged to amply justify sanitary legislation and expenditure."*

The one hundred years have just passed since Jenner's observations and experiments in Gloucestershire† associated his name inseparably with the amelioration of small-pox. Fifty years later Ehrenberg and Dujardin studied and described the various forms of monas, vibrio, spirillum, and bacterium, and the century hardly rounded before Schwann had shown that these bacteria are the cause of the putrefaction of organic substances, and Pasteur had extended this discovery so as to create the belief that all putrefactive changes are due to such minute organisms, when Lister had developed his antiseptic method based on these discoveries; when Koch propounded his theory that tubercular consumption was due to the bacillus; when erysipelas and glanders and splenic fever and malignant charbon were shown to be

* Erected 1879.

+ 1775.

due to special types of bacteria,* and Pasteur had inoculated the attenuated virus of malignant charbon as a protection to cattle and sheep from attacks of the severe forms of the disease, the immense importance of which discovery has been confirmed, this present year, by a report presented to the Veterinary Society of the Department of Eure-et-Loire, showing that these vaccinations, practiced on a large scale, had reduced the annual loss on these flocks from nine per cent. to $\frac{55}{100}$ of one per cent.† The ink is hardly dry from the presses that announce that Lacerda has discovered the yellow-fever microbe, Ziehl the micrococcus of pneumonia, Koch the special bacterium of cholera, Eschbaum the micrococcus of gonorrhœa, Klein of diphtheria, Pohn-Pincus of scarlet fever, Leyden of cerebro-spinal meningitis, Fehleisen of erysipelas, and Linard the bacillus of malarial fever, the intermittent activity of this latest "find" receiving a prompt quietus when immersed in a two-per-cent. solution of quinine—a baptism that would not involve regeneration to much more highly organized creatures. Whether all these and their similars are to stand the test of propagation by "pure culture," and wheel into the prophylactic column, who can say? But it would be a risk to cast their horoscope. Whether the time is ripe to hang a man on microscopic evidence, or whether the time will ever come when the special vibrio of the assassin shall be diagnosed from the spore of the burglar and the zoön of the concupiscent, are not questions angrily struggling for a reply. Humiliating as it has been to know, during the centuries, that "all flesh is grass," the sentimentality of human affection is entirely upset as the apparent universal distribution of these swarming micro-organisms support the scientific accuracy of Festus when he informed his Helen that

"The worm shall trail across thy unsunned sweets,
And fatten him on what men pine to death for;
Yea, have a further knowledge of thy beauties
Than ever did thy best-loved lover dream of."

Original Communications.

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.‡

By FORDYCE BARKER, M. D., LL. D.

DURING the five years which I have had the honor to occupy this chair I have never before seen a meeting of this Academy so enthralled by the charm of elocution, the fascination of rhetoric, the glow of conviction, and the air of one who speaks by authority—an air which can never

carry weight unless it has been before fairly and justly earned by good work—as on the evening of December 6th, when the paper was read on "The Prevention and Treatment of Puerperal Fever."

Its authoritative tone, its earnestness and sincerity, its coloring of being based on experience and observation, instead of being unconsciously deduced from preconceived theory, give the paper such a plausible air of scientific truth as must secure its acceptance without question by many minds whose belief rests on authority, without examination of the data or analysis of argument. The more eminent the author of errors which may dangerously influence medical practice in matters of such vital importance as the saving of life of those who have just become mothers, the more striking the literary excellence and the more admirable the artistic merits of a paper promulgating such errors, the more necessary it is that such errors should be boldly met and promptly refuted. Any paper read before this Academy, by one to whom all concede a place among the most eminent in the department of the profession to which his life has been devoted, if allowed to pass without examination and discussion, will be accepted by great numbers in all parts of the country as a statement of the science and medical practice as enunciated by the most prominent men of the period. It is therefore a duty to carefully examine those novelties in doctrine and in practice which are brought here, and subject them to the test of the advanced science of the day and the accumulated experience of the past.

I will mention one other reason which has had a strong influence in overcoming my reluctance to do this work, and that is in the interest of the Academy.

In view of some past controversies outside of the scientific aims of this body, it seems to me desirable and important that the profession at large should understand that in his hall there can be the strongest antagonism in scientific doctrines and in questions of practice, and the keenest encounters in intellectual gladiatorship, carried on with all the courtesy of the duello, without individual hostility or the interruption of personal friendship.

I think most present know the great reluctance which I have to writing, especially the mechanical part—and that other engrossing work leaves me little time for this, except what should be passed either in rest or in recreation, and will therefore thoroughly appreciate the great reluctance with which I have undertaken the duty.

All will agree that the paper was remarkable for its originality, in that some of its pathological doctrines and the practice inculcated for the prevention and treatment of puerperal fever have never been taught in any work on obstetrics, or by any writer of acknowledged repute. If they are accepted by the common intelligence of the profession, they will assuredly be found in the obstetrical works of the future.

As there are many others who will take part in this discussion, whom all will be anxious to hear, and as the author of the paper is entitled to all the time he may wish to close the debate, I shall, in the most concise language consistent with clearness of statement, give my reasons for thinking that the whole tone and coloring of the paper are mislead-

* Professor Lankester's Address, in "Science," October 12, 1883.

† "Med. and Surg. Reporter," August 17, 1883.

‡ Read before the New York Academy of Medicine, February 7, 1884, at the adjourned discussion of the paper on this subject by T. Gaillard Thomas, M. D., which was read before the Academy December 6, 1883, and published in full in the "New York Medical Journal," December 16, 1883.

ing and dangerous, because it is supersaturated with septic infection. I would not "speak disrespectfully" of puerperal septicæmia. I believe it to be one of the most dangerous incidents which may occur to women after childbirth, and I trust that it will not be regarded as indelicate if I allude to the fact that in a work on puerperal diseases, published more than ten years ago, a lecture devoted to the consideration of this subject in all its relations fills thirty-seven pages. With the most anxious desire to correct any errors of opinion, and to accept any new views which progressive science or increased and more accurate clinical observation has demonstrated to be true, I have yet found no reason to make any essential change of the views expressed in that lecture.

In the paper which we are now to discuss, the author distinctly avows his belief, without any qualification, that "puerperal fever is puerperal septicæmia," and that "it matters not whether it assume the form of metritis, phlebitis, cellulitis, peritonitis, or lymphangitis, the essence of the disorder is a poison, which is absorbed into the blood of the parturient woman through some solution of continuity." Not only the sentence quoted, but the whole tenor of the paper must convey to the unbiased mind that it is the well-defined opinion of the author that metritis, phlebitis, peritonitis, and cellulitis are never seen in the puerperal woman except as the result of an initial lesion, which permits the absorption of a specific poison through the parturient canal, either from the atmosphere or from direct infection by doctors or nurses from neglect or carelessness, or other agents brought in contact with the sexual organs.

The tendency to this pathological view has been rapidly growing within the past few years, as a result of the enthusiastic interest excited chiefly by the important investigations of our German co-workers, who have so zealously studied the character and effects of the micro-organisms in puerperal women in hospitals. In several of the most recent and the most excellent systematic works on obstetrics I have observed that nothing is said of the various local phlegmasiæ which are liable to arise in puerperal women as a consequence of parturition, and that they are only alluded to in connection with the subject of septicæmia. This seems to me a very grave omission, which must seriously embarrass young obstetricians, who consult these works for information when normal convalescence is interrupted by any of the local inflammations. No one, as yet, has maintained that the process of parturition and the puerperal state exempt a woman from those causes which induce local inflammation in the non-puerperal, or will deny that the process of parturition, and other attendant conditions besides the absorption of septic poison, may be the efficient cause of local inflammation; and I here state my conviction that in private practice, when there is no epidemic influence, twenty cases of local inflammation, due to such causes, will be met with where one will be found due to septic absorption.

It is hardly necessary to say, as I have before expressed the same opinions in a work published some years ago, that I am in entire accord with the author in his preliminary remarks as to the peculiarities in the system of puerperal

women. I suppose that all educated men now know that the blood of a pregnant woman is in a state of hyperinosis, and that, as a rule, "her nervous system is in a plus state of sensitiveness and excitability, and influences which are very controllable in the non-puerperal state produce very evil results here." But it is very evident that in certain points our opinions are wide apart. He regards certain conditions, which always are found following normal labor and always occur in normal puerperal convalescence, as pathological, but which I believe to be purely physiological.

The ancients believed in the poisonous nature of the menstrual fluid. Pliny described the menstrual fluid as a "fatal poison—which corrupts and decomposes urine, deprives seeds of their fecundity, destroys insects, that it blasts the garden flowers and grasses, and causes fruits to fall from their branches."

I had supposed this superstition to be extinct until informed by a letter from my friend, Dr. Weir Mitchell, that he knew "old men who would not permit a woman to enter their wine-room, for fear that, if menstruating, it would injure their wines." He also informed me that "in Roquefort women are not allowed in their cheese cellars." I suppose the theory must be that menstrual bacteria will destroy the bouquet of the Roquefort cheese.

But on the evening of December 6, 1883, in this Academy of Medicine, I first heard the full evolution of this doctrine clearly enunciated. The lochia are described as an offensive fluid, made up of dead and decaying animal tissues, which poisons freshly made unprotected wounds. I quote textually two paragraphs:

"In every case of child-bearing the endometrium is thus encumbered, and freed by a process of exfoliation and sloughing; in every case the cervix, vaginal mucous membrane, perineum, and vulva are, in varying degrees, lacerated; and in every case the offensive fluid, called lochia, poisons these freshly made, unprotected wounds."

Again the writer says: "Here we have a number of recent wounds constantly and unavoidably bathed with a fluid made up of dead and decaying tissue, animal tissue in a woman whose blood and nerve states are, with reference to septic disease, like flax prepared for the spark, and who is exhausted by pain, anxiety, loss of blood, and deprivation of sleep."

Other quotations might be given of a similar tenor, and the prophylactic measures, which he asserts "should be adopted in all midwifery cases, whether they occur in hospital or in private practice," are based mainly on this theory.

Can it be true that the process necessary for the birth of the human race is always attended with the development of a deadly poison whose malignant effects must inevitably prevent the spontaneous and kindly healing of such little traumatisms as always result from the process, and that, therefore, it is the duty of the accoucheur to take preventive measures of the character proposed? Does every parturient woman, in performing the function of maternity, like the scorpion,* that carries in its tail an agent for suicide, if

* The late Professor William H. Van Buren used to narrate that, when a surgeon in the army and stationed in Florida, he had often seen the soldiers amuse themselves by placing a scorpion within a

death is threatened by fire, physiologically generate an equally fatal poison in a corresponding locality, which the obstetrician must guard against by means that are most inconvenient, alarming, and not altogether free from danger!

I do not intend now to examine the question, which I have before discussed very thoroughly, and my views have long been published, whether there is not a distinct disease, most appropriately denominated puerperal fever, when, if there be any septicæmia, it must be a consequence of a primary disease, and not a cause. Nearly a hundred years ago the eminent obstetrician of London who succeeded Denman, Dr. John Clarke, wrote as follows in regard to puerperal fever: "Unfortunately, the uniformity of the disease was assumed, and each author erected his own experience into a standard, by which to judge of the descriptions and the practice of others." This observation, which I read early in my professional life, made a strong impression on my mind. I trust that it will not be deemed egotistical that it had great influence on my mind during the twenty-five years that I was engaged in teaching medical students, as I felt strongly the responsibility of the position, and that I should be culpably negligent in my duty if I simply gave the results of my own observations, or the opinions of a limited number of observers, or the theories of a few popular authorities, but that I was bound to give the sum of the knowledge which had become a part of the common stock of the profession. For reasons which will be obvious, I felt this more strongly in regard to puerperal fever than any other subject which I had to discuss either before medical students or in medical societies. More has been written on this than on any one disease. It has been a terribly fatal disease in lying-in hospitals in all the great cities where such hospitals are found. It has been fatal as an epidemic in rural districts, where within a certain area every woman in a sparsely settled population, who gives birth to a child, for a certain limited period is affected, and a large proportion die. I could refer to very many published reports of such epidemics which have occurred in villages and towns where for twenty-five or thirty years previous not a single death has occurred in childbirth except from the casualties of labor, such as rupture of the uterus, hæmorrhage, and convulsions.

All we know of any disease is derived from the study of its ætiology, its clinical phenomena, and its anatomical lesions. The epidemic disease to which I have just referred differs in all characteristic points from what is known circle of fire. After vain and frantic efforts to escape, it would stop, strike its tail into its head or body, and instantly die.

Byron refers to these insect Catos in the following lines:

"The mind that broods o'er guilty woes

Is like the scorpion girt by fire,

In circle narrowing as it glows,

The flames around their captive close,

'Till, inly scorched by thousand throes,

And maddening in her ire,

One sad and sole relief she knows:

The sting she nourished for her foes,

Whose venom never yet was vain,

Gives but one pang, and cures all pain,

And darts into her desperate brain."

—*The Giaour.*

as septicæmia. It differs in its origin, its modes of attack, its symptoms, and its anatomical lesions. The symptoms are frequently manifested a day or two before or even during labor, even when the child is subsequently born alive. In septicæmia the symptoms are never observed before or during labor, except when the fetus is putrid. The former disease, puerperal fever, originates from epidemic causes, and from contagion and infection. The latter, from nosocomial malaria, from autogenetic infection, and from direct inoculation. Can a woman after childbirth be exposed to the danger of receiving the poison which produces septicæmia in larger doses than when she has retained in her uterus a portion of putrid, decomposed placenta? Yet I do not believe there is a single person who has had considerable obstetric practice for twenty years who has not had more than once to remove portions of putrid placenta which has been retained for days, and the patient has had no disturbance of such severity that he would call it puerperal fever. In the Texas "Courier-Record," December, 1883, Dr. H. C. Ghent, of Belton, Texas, gives an amusing report of a case to which he was called three days after labor. She was attended during labor by an ignoramus, who appears to have used considerable force, and probably made some efforts to extract the after-birth. The patient, before he left, called his attention to something like a cord protruding from the vagina, which he said would, perhaps, come away by piecemeal. On his visit the next day, he at first said that a protrusion from the vagina was a false conception, but afterward pronounced it a falling of the womb, which, after a considerable length of time, he succeeded in replacing, and had the anxious husband engaged for twelve hours in constructing an abdominal supporter. On the third day, Dr. Ghent removed a large portion of the placenta and membranes, a putrid mass, with a stench which "was about as much as an ordinary pair of olfactory nerves could well bear." The patient had a quick pulse and high temperature, the constitutional disturbance was easily allayed, as it seems that a "few thorough washings with hot carbolized water" was all the treatment required.

(To be continued.)

ON THE VALUE OF INTERNAL CESOPHAGOTOMY

IN THE TREATMENT OF CICATRICAL STRICTURE.*

By HENRY B. SANDS, M. D.,

PROFESSOR OF THE PRACTICE OF SURGERY IN THE COLLEGE OF PHYSICIANS
AND SURGEONS, NEW YORK; SURGEON TO THE ROOSEVELT HOSPITAL.

My object in the present paper is to consider the value of the operation known as internal cesophagotomy, and to give the particulars of an aggravated case of stricture lately under my care in which this procedure was carried out with a gratifying amount of success. My remarks will relate only to that form of stricture denominated simple, fibrous, or cicatricial, inasmuch as the operation in question is one of doubtful utility in cases of stricture due to the development of a malignant growth.

* Read before the New York Surgical Society, January 22, 1884.

Simple stricture of the œsophagus is probably always preceded by inflammation or ulceration of one or more of its component layers. Systematic writers describe a number of varieties of inflammation—such as catarrhal, syphilitic, phlegmonous, and traumatic—any one of which may lay the foundation of stricture. From an ætiological point of view, however, œsophageal strictures are distinguished by the fact that a vast majority of them are due to the reactive inflammation which follows contact with some highly corrosive liquid, such as sulphuric, nitric, or hydrochloric acid, or a concentrated solution of caustic potash. A consideration of the effects produced by these substances, when accidentally or intentionally swallowed, is essential to a correct appreciation of the pathology and treatment of the lesions that may ensue. These effects vary greatly in different cases, according to the amount of the liquid taken and its degree of concentration. They may be limited to a part or the whole of the œsophagus, or may also extend to the stomach. If the poison is undiluted, and the quantity large, death usually occurs soon after the injury, in consequence of sloughing inflammation of the stomach and œsophagus. The slightest lesion observed consists in a destruction of the epithelial lining, which is soon cast off and regenerated. The cases that possess a surgical interest lie between these extremes. The destructive action may be restricted to the œsophageal mucous membrane, or may involve the subjacent connective tissue, or even the muscular coat. It may be confined to a very short portion of the tube, or may extend throughout its entire length. Furthermore, it may include a part or the whole of its circumference. Accordingly, when the substance which has been destroyed and cast off is replaced by adventitious fibrous tissue, one or more strictures will result, varying in situation, character, and extent. Avoiding details, which are familiar to all, or which are irrelevant to the present discussion, I would draw attention to certain points of contrast between several recognized varieties of stricture, which have an important relation to the prognosis and treatment of the disease. *Ceteris paribus*, the gravity of a stricture will be greater in proportion to its length. And when we remember that a narrowing of any considerable portion of the length of the œsophagus rarely takes place unless the corrosive action of the poison has been intense, and that the long, tubular strictures which result therefrom are usually dependent upon the production of an abundant quantity of cicatricial tissue and are correspondingly narrow, indurated, and unyielding, as well as often tortuous, we can readily understand why, as a rule, such strictures are amenable neither to dilatation nor to internal division, but demand gastrostomy, as the only available means of prolonging life.

Provided a stricture is permeable to instruments of moderate size, its length can usually be ascertained by the use of a bulbous bougie. The upper limit is indicated when the bulb meets with resistance before it enters the stricture, and the lower limit as it again encounters resistance on being withdrawn. Œsophageal strictures, as I have already stated, vary greatly in their longitudinal extent, and, classified according to their variations in this respect, they may, like strictures of the urethra, be spoken of as linear, annular, or

tubular. Another variety of stricture is that in which the cicatricial tissue is of limited horizontal extent, so that it does not embrace the entire circumference of the œsophagus. It may then form a more or less rigid, valve-like projection against the opposite unaltered wall, causing the orifice of the stricture to have an eccentric position. Trélat,* in 1870, proposed to diagnosticate this peculiar condition by means of a demi-bulbous bougie, whose expanded extremity is flat on one side and convex on the other. By introducing the bulb beyond the stricture, and presenting its convex surface toward different parts of the circumference of the œsophagus while making successive attempts to withdraw it, the situation of the callous deposit may be determined by feeling the greater resistance which it opposes to the withdrawal of the instrument. The practical application of the information thus obtained will presently be apparent.

Perhaps I can adopt no better plan of stating my own views regarding the value of internal œsophagotomy as a surgical expedient than by combining them with the record of a case in which I have recently performed the operation:

Addie B., aged eight years, came under my care on January 10, 1883, having been sent to me by Professor William H. Doughty, of Augusta, Ga., in the hope that something might be done to relieve her of an œsophageal obstruction which had been caused by the accidental swallowing of a mouthful of a strong solution of caustic potash on September 27, 1882. No alarming symptoms immediately followed the accident, but deglutition was always afterward more or less difficult and painful, rendering necessary a fluid diet, which consisted chiefly of milk. Dysphagia began to be severe early in November, and was attended with rapid emaciation, the child's weight having been reduced from 44 to 41 pounds in the week preceding November 16th. Subsequently a slight improvement took place; but toward the end of December the patient's condition grew very alarming, and it was found necessary to resort to rectal alimentation. Early in January, dilatation of the stricture was attempted; no progress was made, however, and, fearing that the child's situation might at any time become desperate, Dr. Doughty recommended that she should be brought to New York, for the purpose of being benefited, if possible, by surgical treatment. At the time of my first visit, on January 10th, I found her very weak, emaciated, and dejected; and evidently threatened with death from starvation. Deglutition had become almost impossible, and the rectum had become somewhat intolerant of enemata. On exploring the œsophagus, I discovered a tight stricture, situated nearly opposite to the middle of the sternum, at a distance of eight inches and a half from the incisor teeth. The stricture was impassable to instruments, and the daily attempts I made to penetrate it were unsuccessful until January 16th, when I was able to introduce a filiform whalebone bougie, having a diameter of two thirds of a millimetre. During the ensuing five months dilatation was practiced almost every day, but made very slow progress, as is shown by the following record:

January 24th.—Passed elastic bougie No. 6. (F.)

February 1st.—Passed No. 9. (F.)

3d.—Passed No. 11. (F.)

29th.—Passed No. 12. (F.)

March 15th.—Passed No. 13. (F.)

April 11th.—Passed No. 14. (F.)

* "Bull. gén. de thérapeutique," Paris, 1870, p. 282.

27th.—Passed No. 15. (F.)

May 8th.—Passed No. 16. (F.)

28th.—Passed No. 17. (F.)

On February 1st I succeeded in introducing an elastic catheter having a diameter of three millimetres, which proved large enough to allow the injection of milk into the stomach whenever the child was unable to swallow. Until this time her condition had been extremely precarious, and the question of performing gastrostomy was more than once debated. But, on the one hand, the patient seemed too feeble to bear the operation, and, on the other, her father's repugnance to such a procedure was invincible. Later the dysphagia diminished, so that she was able to swallow an abundance of fluid food consisting of milk, soup, and raw eggs, and toward the end of May it was found that she had gained twelve pounds in weight since her arrival in New York. Nevertheless, it had meanwhile become evident that the stricture was of the most obstinate character; for, whenever a single day passed without an attempt to dilate it, a contraction would take place, rendering necessary the use of smaller instruments, the employment of which sometimes caused considerable pain. Being convinced that further treatment by dilatation would be useless, and perhaps dangerous, by allowing accidental injury to the œsophagus, I decided to resort to internal œsophagotomy as the most promising expedient under the circumstances.

I was encouraged to anticipate success from the operation in the present case especially in view of two considerations: First, I had ascertained, by careful explorations made with demi-bulbous bougies, that the stricture was due to the presence of a narrow ring of fibrous tissue, occupying only a quarter of an inch of the length of the canal. Secondly, on introducing beyond the stricture an instrument which I devised for the purpose of examining the deeper parts of the œsophagus, and which is constructed on the same principle as Dr. Weir's urethrometer, I found that when the bulb was expanded to its utmost limit—No. 28 (F.)—no other contraction could be detected. Accordingly, it appeared probable that great benefit must result from internal division of the stricture, provided this could be safely accomplished. But the operation is well known to be hazardous; and, perhaps for this reason, it has been rarely undertaken since it was performed, for the first time, by its inventor, Maisonneuve, in 1861.* Mackenzie,† who published, a few months ago, an interesting article containing the statistics of internal œsophagotomy, was able to cite only eleven cases in which this operation had been performed for cicatricial stricture; and of these three, or 27·28 per cent., proved fatal. The operation is condemned by many surgical writers, and is not even mentioned in some of our popular textbooks. When we reflect, however, that the natural termination of this disease is death by starvation; that there are many cases like the one herewith reported which baffle the most patient attempts at dilatation; that the operation required to establish an artificial opening in the stomach, for the purpose of feeding, is one which is likewise dangerous, and which, even when successful, places the patient in a deplorable condition, and can not be contemplated without some feeling of disgust; and that, finally, internal œsophagotomy is an operation which aims to re-establish a function so important as that of deglutition, we must acknowledge that it merits the most attentive study, with the view of determining the class of cases to which it is applicable, and of adopting the safest and most efficient method of performing it. Undoubtedly, the cases most favorable for the operation are those in which there is only a single stricture, of slight longitudinal extent. Conversely, little hope of benefit from it can be entertained when the stricture is long, tortuous, and indurated. We notice here a close analogy between strictures of the urethra and those of the œsophagus. In bad cases of urethral stricture, however, which are not curable by internal division, we can often resort with success to external urethrotomy, while external division is a procedure very rarely adapted to œsophageal stricture, on account of the usually inaccessible situation of the affected parts.

The dangers of internal œsophagotomy depend on the important relations of the gullet. In different parts of its course it is in close proximity to the pneumogastric and the recurrent laryngeal nerves, the trachea, the left bronchus, the pericardium, the aorta, the azygous vein, and the pleura. The loose connective tissue behind the œsophagus is prone to suppurate when injured, or when food or other irritating substances come into contact with it. Some of the risks attending the operation may be gathered by a perusal of the recorded cases. In Maisonneuve's hands two proved fatal from peritonitis, apparently not dependent on the operation, as at the autopsy the incisions were found not to have passed beyond the limits of the callous tissue, while the surrounding parts were free from inflammation. Braun* conjectures that in both these cases the stomach may have been accidentally perforated by the metal conductor which forms a part of the œsophagotome, although Maisonneuve alleges that no such perforation could be discovered on careful examination. Trélat's patient had severe hæmorrhage after the operation; and death, in a case related by Schilz, was probably due to this cause. In Czerny's case, the incision doubtless perforated the œsophagus, for emphysema of the neck was noticed a few hours subsequently to the operation, and after death a large abscess was discovered in the posterior mediastinum, communicating with the œsophagus and with the right pleural sac. Likewise, in a fatal case recorded by Mackenzie, pneumonia supervened soon after the operation, and, at the autopsy, a purulent collection was found in the right pleura. Omitting further allusion to Maisonneuve's cases, in which there is no demonstrable connection between the fatal event and the operation, it is evident that the chief danger of internal œsophagotomy is either that of accidentally cutting the healthy vascular tissues, thereby causing hæmorrhage, or of making the incision so deep as to injure one or more of the important parts with which the gullet is in relation. An ideal operation, therefore, would be one in which the cicatricial tissue alone is divided, and in which the peri-œsophageal structures are left intact. We are thus led to examine the different methods which have been employed, in order to ascertain to what extent these requirements have been fulfilled.

* Maisonneuve, "Clinique chirurgicale," Paris, 1864, tome 11, p. 409.
† "Ann. Jour. of the Med. Sci.," 1883, vol. lxxxv, p. 420.

* Czerny, "Beiträge zur operativen Chirurgie," p. 76.

† "Bull. gén. de thérapeutique," 1870, p. 259.

Maisonneuve's instrument is similar in principle to his well-known, admirable urethrotome. It has a conductor, consisting of a slender, flexible bougie, to which is attached a flattened steel guide, four millimetres in breadth, and grooved on opposite sides to receive the blades. The latter are two in number, each one being twelve millimetres in breadth, of triangular shape, and having a cutting edge limited to its anterior third, the remainder being quite blunt. The guide having been introduced through the stricture into the stomach, one of the blades, the edge of which is directed laterally, is passed slowly and gently along the conducting groove until it reaches the stricture, when it is advanced with a sufficient degree of force to overcome the resistance. The second blade is then introduced in the same manner, making an incision through the opposite side of the stricture; finally, the entire instrument is carefully withdrawn.

Studsgaard employed an instrument resembling Maisonneuve's, but having a concealed double-edged blade.

Lannelongue's œsophagotome also resembles Maisonneuve's, but it has only a single blade, which is protected by a sheath. The projection of the cutting edge is fifteen millimetres.

Trélat invented an instrument by which he divided the stricture by cutting from below upward. It is provided with two blades, each being four centimetres in length, and concealed within a metal tube four millimetres in diameter and six centimetres in length. By turning a screw in the handle of the instrument, the blades can be projected to any distance not exceeding two centimetres. Owing to the length of the blades, they have a very gentle slope, which facilitates their passage through the tissues that require to be divided.

Dolbeau operated by the retrograde method, using an instrument provided with a conical tip, in which were concealed two lateral cutting blades. The bulb was made just large enough to pass through the stricture, and the blades could not be projected beyond the diameter of the cone.

Czerny and Mackenzie have also performed the retrograde operation with instruments of their own invention, each being furnished with a single blade.

On comparing these several instruments, it will be found, in the first place, that some are arranged so as to cut from above downward, while with others the incision is made from below upward. Recent writers have invariably, and perhaps rightly, condemned all instruments belonging to the former category; but their objections do not seem to me the strongest that might be offered. Whether the incision is made from above downward, or in the contrary direction, is of itself a matter of little moment. It has been said that, when the incision is made by thrusting the knife downward, the œsophageal wall below the stricture is especially liable to be perforated; but I can not understand why this should happen without carelessness on the part of the operator, nor am I acquainted with any clinical or pathological evidence in support of this assertion. The great disadvantage of the anterograde operation seems to be the necessity of introducing a sharp metallic guide considerably beyond the stricture before the blade can be safely used. This ma-

nœuvre was found to be extremely difficult by both Maisonneuve and Lannelongue, and it must be attended with no slight risk of causing perforation. In operating by the retrograde method this danger is diminished by the flexibility of the instrument employed, as well as by the circumstance that its extremity can be made blunt, and need not be introduced far beyond the seat of stricture. On the other hand, in a case of stricture of very small caliber, Maisonneuve's operation would have the advantage that it could be performed with a guide not exceeding two millimetres in diameter, while an instrument intended to cut from below upward can hardly be made with a diameter less than four millimetres.

A second difference to be noted is that some instruments are provided with only a single blade, while others have two blades, so arranged as to cut in on opposite sides. There can be no doubt that the safety of the operation is increased when only one blade is employed, which can be directed with precision toward any part of the circumference where division of the cicatricial tissue is indicated.

The last and most important contrast to be observed is the different depth to which the incision is extended, or may be extended, with different instruments. This is very great, Dolbeau's instrument, for example, being so constructed as to permit mere scarification, while in that employed by Trélat the distance between the cutting edges of the two blades, when fully projected, is two centimetres. In endeavoring to estimate the relative value and safety of shallow and deep incisions in the treatment of stricture of the œsophagus by internal division, we must take into account certain facts revealed by pathological anatomy. It is well known that in strictures of equal caliber the thickness of the fibrous material on which the constriction depends varies greatly in different instances. Thus, a stricture which will admit only a filiform bougie may be owing to the presence of a narrow ring of cicatricial tissue not exceeding one or two millimetres in thickness, while in another stricture of the same caliber the thickness of the constricting band may exceed a centimetre. It is evident that in the former case a shallow incision would relieve the constriction, and that in the latter a deep incision would be required for the same purpose. It is also plain that in the former case a deep incision would be liable to extend beyond the outer circumference of the œsophagus. Indeed, this accident occurred and proved fatal in Czerny's patient, although the incision was only two millimetres in depth. Unfortunately, we have no means of determining in the living subject the exact thickness of the callous deposit, and are, consequently, left in uncertainty regarding the needful depth of the incision in any given case. A shallow cut may be useless; a deep one may be fatal. Notwithstanding our want of knowledge as to the condition of the diseased parts, we may, I think, proceed in such a manner as to overcome the constriction without subjecting the patient to any extraordinary risk. As, in spite of every precaution, the edge of the knife may possibly be directed against some part of the œsophagus which has undergone no morbid change, the depth of any single incision ought to be a trifle less than the thickness of its coats, which sometimes does not

exceed two millimetres. Assuming that the stricture is annular, we may make a superficial incision at any point of its circumference, and afterward endeavor to effect dilatation by the introduction of sounds. If we have succeeded in dividing the whole, or even the greater part of the constricting band, rapid improvement will probably follow. Should little or no benefit result from the first incision, a second one may be made at some other point, where, perhaps, the ring may be thinner and less resistant. In case this fails to cause improvement, still another point may be selected for incision, with, perhaps, a more fortunate result; or it may be found expedient to make a number of incisions in the same plane. Much has been said respecting the comparative safety of cutting in different directions, some operators preferring to cut toward the right side, some toward the left side, while others regard a posterior incision as the only proper one. The relations of the œsophagus vary so considerably in different parts of its extent that it is impossible to lay down any rule which would apply to all cases. Perhaps, in a general way, it may be affirmed that an anterior incision is the most hazardous, and a posterior one the least so; but, if we adopt the precaution of avoiding incisions of sufficient depth to penetrate the entire thickness of the œsophageal wall, we may turn the edge of the knife toward any point without incurring much risk of wounding important parts.

(To be concluded.)

THE NECESSITY OF PRIMARY PERINEORRHAPHY.*

By CHARLES R. CRANDALL, M. D.

PORTLAND, ME.

(Concluded from page 124.)

Having noted thus far the position and function of the perineal body, the conditions tending to cause its rupture the degrees to which it may be injured, the frequency of the accident, and the means calculated to prevent its being ruptured, let us advance to a consideration of the dangers which may result if the injury does occur and is not promptly corrected. To systematize, I shall refer to the possible dangers as being:

1. Immediate.
2. Secondary.

(1) In the first place, after the rupture of the perinæum to any extent there is the immediate danger of delayed convalescence.

(2) There is the almost immediate danger of contagious infection, septicæmia, and puerperal fever. Force and contusion have torn the natural structures asunder, and in this condition blood-vessels stand open, lymphatics are lacerated and exposed, muscular fibers are separated, and thus is presented a condition favorable, in the highest degree, to sloughing and absorption. Moreover, at this peculiar period the puerperal woman is highly susceptible to the invasion of disease. In all probability her strength is impaired, her nerves depressed from anxiety and shock, her blood

hyperinosed and possibly anæmic, and her genital tract and cervix uteri abraded and lacerated. Under such predisposing conditions, how great is her danger when she must lie for days with a constant stream of morbid exudate, composed of decomposed blood, dead cells, and putrid serum, moving sluggishly over the raw surfaces of her ruptured perinæum!

But to-day there are many who maintain that these dangers are largely visionary, and that, if necessary, they can, in a great degree, be avoided, without resort to an operation, by cleansing the parts, keeping the patient's legs together, and thus favoring union by first intention. But the beauty of this objection is badly marred when one obtains an idea of the number of women who, treated thus, either perish or else, after suffering for a long time, are obliged to submit to a secondary operation. And the theory receives another blow when an eminent authority declares to the profession that "out of thirty cases in which no operation was performed there was only a single one in which union occurred to such an extent that the perineal body was entirely restored; in the twenty-nine there was but slight union." (Garrigues, "The Medical Record," March 20, 1880.)

2. The secondary dangers having origin in a ruptured and neglected perinæum are indeed many.

(1) In the first place, there is the danger of great discomfort and dissatisfaction to the patient. When she arises from her lying-in bed she feels a sense of uneasiness and a dragging-down sensation, which becomes a serious annoyance, and one to which few women ever become kindly accustomed.

(2) There is the almost positive danger of prolapsus uteri and, sooner or later, retroversion. The vagina being large and relaxed, the natural support of the generative organs being destroyed, displacements of some kind follow as an almost inevitable sequence. With displacements, follow, in turn, that miserable *ensemble* of symptoms described as a "bearing-down feeling," frequent desire to urinate, "burning and irritation," inability to stand long or walk far, backache and sideache, neuralgic pains, etc.

(3) A third danger is, that, as the parts become more relaxed from pressure and senile atrophy, there will ensue a prolapse of the bladder, vagina, and rectum, with all the miseries attending those distressing conditions.

(4) If the laceration is complete, there necessarily follows a loss of control over the rectum and anus. Fæcal material and intestinal gases will escape involuntarily, and, as a result, the patient becomes alike disgusting to herself and offensive to her friends.

(5) The danger of a loss of the sexual desire, and the mental misery common to such conditions. It is not uncommon for women whose perinæum is destroyed to complain of loss of sexual desire. Nor is it uncommon to have husbands complain of absence of emotion and imperfection of physical conditions on the part of the wife. Indeed, estrangements have resulted due to a ruptured perinæum, and households have been ruined.

Lastly, there are the secondary dangers of impairment of general health, indigestion, emaciation, nervous disease, neurasthenia, and anæmia. True, all of these dangers do

not develop in every case to the extent described, but there is a possibility that such may be the case, and hence they should be guarded against in every possible manner.

From the dangers that may follow as a sequence to a ruptured and neglected perineum, let us note for a moment the great advantages resulting from a successful primary operation:

1. The operation being successful, the patient arises from her confinement at an early day, feeling practically in a natural condition, as far as her pelvic organs and perineum are concerned.

2. The raw surfaces being covered in and placed in a condition to unite and heal, the patient is guarded against the dangers of septic absorption.

3. Lastly, she is largely protected against the secondary evils incident to a ruptured perineum—such as “uterine displacements, prolapsus, cystocele, urethritis, uterine engorgement and hyperplasia, subinvolution of the uterus and vagina, destruction of the power of the uterine ligament, development of a tendency to abortion, impaired sexual gratification, and neuralgia affecting the site of the rupture.” (Thomas.)

To return to a consideration of the primary operation proper, it will be worth our while to have definite ideas regarding the degree of laceration that requires operative interference. Upon this point there is a great and bewildering diversity of opinion. Some claim that a laceration of more than half an inch into the perineum should be closed promptly with one or more sutures, while others do not believe in interfering with any laceration unless it be complete, and such they would postpone for secondary operation. By way of illustration, it may be said that, in a recent discussion on this important subject in New York city, Drs. Gillette and Little advocated the view of closing every rent by immediate operation; Dr. Lusk claimed that not all cases of slight laceration necessitated the introduction of sutures, but he favored the primary operation when necessary, while Dr. Wood was not in the habit of performing the primary operation, and believed, besides, that lacerations to the first or second degree invariably recover, leaving the parts as normal as they ever are after childbirth. (“Medical Record,” December 1, 1883.) And there are physicians who, after many years of general practice, still ridicule the necessity for an immediate operation upon a ruptured perineum of any extent. They say that a moderate rupture will take care of itself, that they never saw the dangers resulting therefrom that a young practitioner sees, and that they look upon all such performances as being “meddlesome midwifery.” But their methods are crying out against them in scores of women seeking relief from misery after many years of suffering which had origin in a ruptured and neglected perineum. Concerning those who were left with a ruptured perineum, and who soon afterward became the victims of septicaemia, God only knows. As is too often said, “They were lost sight of afterward.”

Of course, owing to the great difference in the formation of women—some being large, others small, some being lean, others fat and flabby—it is, indeed, extremely difficult to draw an arbitrary line and say that all ruptures extend-

ing below this line must be closed immediately with one or more sutures. But may it not be laid down as a sound general rule that a rupture extending into the vagina and perineum more than a half-inch, after the parts have contracted, should be closed with sutures? This may be drawing the line too high up, but better this than too low down, for in closing even slight ruptures the obstetrician does no harm, but rather does his full duty, and gives his patient the advantage of the best condition for rapid and permanent recovery.

But it may occur to some to ask, “Are there not instances where contra-indications preclude the feasibility of primary perineorrhaphy?” In reply I would confess that most assuredly there are, and they should be judiciously observed. With this operation, as with all others, circumstances and conditions are to be considered, and all procedures are to be regulated by the probable welfare of the patient. I will not enter into a description of an exceptional case, because they are so few, but will say that they do exist, and the careful, thinking man will sooner or later run across them. The doctrine which it is the object of this paper to help establish is the necessity of primary perineorrhaphy in all suitable cases, and excepting those which would be unsuitable owing to convulsions, excessive hæmorrhage, excessive exhaustion, advanced stages of organic disease, and mania.

Now permit me, as preliminary to a consideration of the *modus operandi* of primary perineorrhaphy, to say that every physician should go to the lying-in chamber prepared to meet this emergency. He should take with him ether, needles, needle-holder, sponges, sutures, scissors, syringe, and disinfectant. Prepared thus, he will be far more inclined to operate, if necessary, and do his full duty.

Now, how shall the operation be performed?

1. Etherize the patient fully. Complete anaesthesia tends to prevent fright, shock, and muscular contraction.

2. Place the patient in the prone position across the bed, with the buttocks drawn slightly over the edge, and have her limbs held by two assistants.

3. Syringe the vagina thoroughly with warm water, and pack it with two or three new and clean disinfected sponges.

4. Control all bleeding vessels by torsion and all oozing by hot sponges, and bring the parts into perfect apposition.

5. Introduce silver sutures with a straight needle, held by a needle-holder. Enter the sutures about half an inch from the edges of the wound. Inclose enough tissue to afford firmness. Have the sutures emerge exactly opposite each other, so that position and pressure will be accurate. Conceal the sutures as much as possible within the tissues of the recto-vaginal septum. Enter the first suture well down below the wound, and the last one a little above the upper edge of the wound. Cover the twisted ends of the sutures with a piece of rubber tubing. Waxed silk sutures or catgut sutures may be used, and do not cause pain when being removed; but silver ones are best, for they cause less ulceration, do not hold septic material, and can be tightened or loosened at pleasure.

6. The wound now being neatly closed, place the pa-

tient in bed, bandage her legs together at the knees, and give her hypodermic injection of one-fourth of a grain of morphia.

Assuming now that the primary operation has been carefully performed, let us note the steps of the after-treatment. It must be borne in mind that careful attention to details, the help of a good, intelligent, faithful nurse, and full co-operation of the patient, are highly essential to the success of the operation.

1. Keep the patient quiet upon her back as much as possible during the first three days, and do not let her sit up during the first ten days.

2. Have the napkins intended to absorb the lochia changed every two hours, and the bedding kept absolutely clean.

3. Have a warm, carbolyzed vaginal injection given every six hours, and see that the nurse knows how to give it. Have the vagina and genitalia thoroughly cleansed after each act of micturition.

4. Allow the patient to use the bed-pan at her pleasure; but, if she is unable to do so, have her catheterized twice daily with a new, clean, soft-rubber catheter.

5. Give her morphia sufficient to avoid pain.

6. Give her a light, restricted, liquid diet, composed largely of animal broths and beef-tea, during the first few days. Milk is objectionable in these cases, for it often generates a great amount of intestinal gas, tends to constipate the bowels, and creates a bulky, scybalous stool.

7. In cases of laceration of the second degree, induce a "soft movement" of the bowels on the third day with a saline laxative and enema of warm water, and insure a similar movement each day thereafter. It was formerly the practice to keep the bowels "locked" for seven or ten days, but it has been found that patients do better and success is greater when the bowels are allowed to move early and daily. In the first and third cases in my own practice, referred to previously, the bowels were moved by the third day, and success was perfect. When the bowels are confined for a week or more there is danger from intestinal irritation, fever, bulky stools, and rectal distension. In cases of complete laceration, all authorities formerly advised keeping the bowels closed for ten days; but now the view is changing, for it has been found that success is most frequent where the bowels move daily after the third day.

8. Keep the temperature of the room at about 70°; have good ventilation; avoid draughts; let in an abundance of sunlight.

9. Do all things to keep the patient cheerful, hopeful, and comfortable.

10. Remove the stitches about the seventh day. It must be borne in mind that union by first intention in the perinæum takes place early and rapidly, if at all, for the parts are held in firm apposition and are highly vascular.

The prognosis of primary perineorrhaphy, when properly performed, is favorable in almost every case. Analysis of a great number of cases has not yet afforded absolute data, but the reports of different men, who have made a practice of performing the operation, furnish us most gratifying intelligence. In illustration, Dr. Page, of New York,

in a recent article on this subject, makes the following statement:

"Of a collection of 100 cases, including all degrees of rupture, 90 were cured, 9 improved, and 1 was not improved." ("Medical Record," December 1, 1883.) And Dr. Lusk, in the same journal, gives his results by saying, recently, in looking over his hospital obstetric record, he found that he had operated in 24 cases, 23 of which were successful, and in 1 there was partial failure, due to a certain amount of carelessness with which the operation was performed. It is evident, then, that well-directed efforts to perform the operation are very likely to be followed by success.

Before concluding my lengthy advocacy of primary perineorrhaphy, I beg to put upon it the indorsement of some of the leading minds of our profession in different parts of the world.

"The operation should be performed just after delivery." (Scanzoni.)

"If it (the perinæum) has given away to any extent, I believe that it is good practice to insert one or two interrupted sutures of silver wire or carbolyzed gut at once." (Playfair.)

"You must therefore make a clean breast of the mishap to the patient, and perform the primary or immediate operation—that is to say, you must at once sew up the wound." (Goodell.)

"If the perinæum be lacerated, it should be closed at once by suture, to shut up this avenue of septic absorption." (Thomas.)

"The primary has been so successful in a large number of cases, and is so simple in its performance, and does so much to prevent the woman from suffering during child-bed, avoid suffering for weeks or months before the secondary operation is performed, that it seemed to him there could be no doubt with regard to the propriety of the primary operation." (Lusk.)

Lastly, the parturient and puerperal state is an epoch attended with great suffering and peril. From the time the woman takes her couch in labor until she has regained her usual state of health, and has resumed the ordinary duties of life, dangers beset her on every hand. The perils of mal-presentation, convulsions, ruptured uterus, ruptured perinæum, hæmorrhage, septicæmia, inflammation, peritonitis, and puerperal fever make up a group that may well cause almost every woman to exclaim, "I know I shall die!" So dreadful, then, are the perils of the birth-giving hour, so solemn and serious is the welfare of the mothers and children and homes all over the world, that every physician who undertakes to conduct a woman through the many dangers of the supreme hour of her life should, as a matter of conscience, measure well the height and depth of his responsibility.

NEW YORK, SATURDAY, FEB. 9, 1884.

THE PROPOSED STATE EXAMINING BOARD.

THE greater portion of the time of the Medical Society of the State of New York, on Wednesday, was taken up with the discussion of this subject, and the conclusion arrived at was in consonance with the opinion we expressed last week—that no specific measure would be pressed upon the Legislature during its present session. Two bills came up before the meeting, each of which was urged with much fervor. One of these bills was substantially an elaboration of the Erie County society's bill, reported on favorably by the Committee on Legislation. The other was a bill prepared and advocated by a number of gentlemen representing the three great colleges of the city of New York. The latter had been very carefully drawn, and contained some excellent provisions, but it so restricted the powers of the proposed board as to render it unacceptable to the active promoters of the plan to dissociate the teaching bodies from the licensing power, some of whom, indeed, looked upon it as in this respect open to the criticisms we applied to a certain bill last week. Its advocates, however, showed a commendable willingness to modify it, and, although the early part of the debate was heated and almost acrimonious, moderation finally arose in each party, and the action reached at the close we must regard as, under the circumstances, most fortunate. A special committee formed of the Committee on Legislation, together with three gentlemen representing as many colleges, was directed to report a bill at the next annual session. From the constitution of this committee, it can not be doubted that a bill will be drawn that will satisfy all reasonable requirements in the case.

THE NEW CODE STANDS.

ONE year ago, under this caption, we announced that the Medical Society of the State of New York had confirmed its new code of ethics at a meeting which, up to that time, was the largest ever held. We have now to record that, on Tuesday last, at a meeting still larger, that action was reaffirmed. On the 6th of February, 1883, the vote on Dr. Squibb's motion to repeal the new code stood ninety-nine ayes to one hundred and five nays; on the 5th of February, 1884, the vote on Dr. Didama's motion to the same purpose stood one hundred and five ayes to one hundred and twenty-four nays—a gain of six votes in favor of restoring the old code, and of nineteen against it.

Thus the society has verified the prophecy we ventured to make in our last issue, that the new code would be reaffirmed, and very likely by an increased majority over that of last year. It seems altogether improbable that this action will ever be reversed, for greater efforts to accomplish that result could not

well be made than have been made already. Up to the time of this writing, no notice has been introduced of any further attempt at its reversal, so that it seems reasonable to suppose that the next annual meeting of the society will not be vexed with the ethical question. We trust, indeed, that the question will never again come up before the society, but that hereafter its sessions may be devoted to the consideration of matters free from the asperities that have characterized the contest now ended.

MINOR PARAGRAPHS.

A NEW STATE SOCIETY.

AFTER the action taken by the Medical Society of the State of New York last Tuesday, whereby the movement to restore the code of ethics of the American Medical Association was defeated, a number of the most prominent adherents of the movement met at the Delavan House, in Albany, and took measures for the organization of a new State society, to be known as the New York State Medical Association. It is understood that membership in any county society will constitute eligibility to the new society. We are not informed that the promoters of the new organization have severed their connection with the old one, and it is to be hoped that they will not do so, for it is in the nature of things that the rancor engendered by the ethical strife will vanish in due course of time.

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 5, 1884:

DISEASES.	Week ending Jan. 29.		Week ending Feb. 5.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	1	1	0
Typhoid Fever	8	2	10	4
Scarlet Fever	90	11	94	12
Cerebro-spinal meningitis	6	4	6	6
Measles	52	14	39	4
Diphtheria	59	20	27	10
Small-pox	1	0	0	0

THE RETIREMENT OF PROFESSOR COURTNEY from the Montpelier Faculty of Medicine is announced.

MESSRS. BIRMINGHAM & Co., the medical publishers, inform us that they have resumed business.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.—We understand that Dr. E. C. Spitzka has resigned, and is succeeded by Dr. Ambrose L. Ranney in the chair of the anatomy and physiology of the nervous system.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 26, 1884, to February 2, 1884:*

ALEXANDER, CHARLES T., Major and Surgeon. So much of Par. 7, S. O. 211, September 14, 1883, as directs him to report in person to the commanding general, Department of the Missouri, for duty, is revoked, and he will, upon the expiration of his present leave of absence, proceed to St. Louis, Mo., and assume duty as attending surgeon and examiner of recruits in that city. Par. 1, S. O. 21, A. G. O., January 25, 1884.

ELBRET, FREDERICK W., Captain and Assistant Surgeon. Present leave of absence extended six months. Par. 9, S. O. 24, A. G. O., January 25, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending February 2, 1884:*

BATTLE, S. W., Passed Assistant Surgeon, detached from U. S. S. Gedney and placed on sick leave.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, February 11th:* New York Academy of Sciences (Section in Chemistry and Technology); New York Ophthalmological Society (private); New York Medico-Historical Society.

Tuesday, February 12th: New York Academy of Medicine (Section in Surgery); New York Surgical Society (private); East River Medical Association (private); Medical Societies of the Counties of Rensselaer and Ulster, N. Y.; Jersey City Pathological Society; Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association (private).

Wednesday, February 13th: American Microscopical Society of the City of New York; New York Pathological Society; Medical Society of the County of Cayuga, N. Y.

Thursday, February 14th: New York Laryngological Society; Harlem Medical Association (private); Brooklyn Pathological Society; Medical Association of the Eastern District of Brooklyn.

Friday, February 15th: Yorkville Medical Association (private).

OBITUARY NOTES.

PROFESSOR REICHEBT, OF BERLIN.—Professor Reichert, whose retirement from the chair of anatomy in the University of Berlin we lately chronicled, died on the 21st of December, after a short illness.

ELISHA HARRIS, M.D., OF ALBANY.—Dr. Harris died on Thursday of last week, in his sixtieth year, after a short illness. He was a native of Vermont, and a graduate of the College of Physicians and Surgeons of the City of New York. For a short time after taking his degree he practiced medicine, but the greater part of his life was spent in executive and statistical work in connection with various sanitary boards. On the organization of the Metropolitan Board of Health, in 1866, he was appointed Registrar of Records, and served the board in that capacity and in others for several years. When the State Board of Health was established he was made its secretary, and held that position up to the time of his death. It is understood that his last illness was a recurrent attack of perityphlitis.

Dr. Harris was a man of pleasing and impressive presence, an ardent laborer in the field of sanitation, and a faithful and untiring public officer.

ADDISON P. DUTCHER, M.D., OF CLEVELAND, OHIO.—Dr. Dutcher died on Wednesday, January 30th, in his sixty-sixth year. He was born in Durham, Greene County, New York, October 11, 1818, and began the study of medicine in 1834, under Dr. John Shanks, of New York, and subsequently entered the office of Dr. Edward H. Dixon. In 1839 he was graduated from the College of Physicians and Surgeons of New York. After practicing in Cooksburry, N. Y., and in Eaton, Pa., for a short time each, he settled, in 1847, in Enon Valley, Pa., where he resided seventeen years. In 1864 he accepted the chair of the principles and practice of medicine in the Charity Hospital Medical College of Cleveland, occupying that chair during two terms of the college.

Since 1864 he has lived in Cleveland, where he was held in high esteem as a practitioner and as a citizen. He has contributed freely to medical literature, and was an earnest advocate of the temperance cause, both as a writer and as a speaker.

He was a Fellow of the Cleveland Academy of Medicine, of

which he was president in 1868, an honorary member and ex-president of the Beaver County, Pa., Medical Society, and an ex-member of the Pennsylvania Medical Society.

Letters to the Editor.

THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL, AND THE QUESTION OF THE ABUSE OF MEDICAL CHARITY.

No. 31 WEST THIRTY-SIXTH STREET }
NEW YORK, January 13, 1884. }

To the Editor of the New York Medical Journal:

SIR: Your editorial, in your issue of December 29, 1883, upon "The Abuse of Medical Charities," and citing the action of the authorities of the London Hospital in their efforts to prevent this abuse, leads me to state that the evils and abuses so much and so reasonably complained of by the profession have been successfully met by the trustees of the New York Orthopædic Dispensary and Hospital. I deem their prompt action worthy of record—especially as you express the fear in your editorial comments that "it may take some time for a London example of this sort to be followed in New York."

The frequent application of persons at the New York Orthopædic Dispensary and Hospital for gratuitous relief who, while professing to be poor, were amply able to pay for professional service, led me to bring the question of the abuse of medical charity before the trustees of the institution at one of their stated meetings over a year ago. I asked that some measures be adopted by which the medical staff could discriminate against these impostors. Prior to the time when the matter was thus officially brought to the attention of the trustees it had been the custom of the medical staff to promptly dismiss all those who were discovered to be able to pay anything for private treatment. But the surgeon in charge felt that many were applying for and receiving treatment who had no right to expect gratuitous services; and it was impossible to know, without some system of investigation, who were the guilty ones.

In my communication to the trustees I cited many facts bearing upon the matter introduced, and named some striking illustrations of the manner in which the charitable objects of the institution had been abused. The subject was fully discussed. The result was that Howard Potter, Esq., president of the Board of Trustees, by an individual contribution, made the Orthopædic Dispensary a life member of the New York Association for Improving the Condition of the Poor. This latter society has an organized system of investigation, and its paid visitors were instructed to investigate any case referred by the Dispensary to them.

The following letter in blank was prepared by the medical staff of the Dispensary, and, having been approved by the trustees, was sent properly filled out, in every questionable case, to the Secretary of the Association for Improving the Condition of the Poor:

NEW YORK ORTHOPÆDIC DISPENSARY,
No. 126 East 59th Street.

New York, 188 .

To the New York Association for Improving the Condition of the Poor:

GENTLEMEN:

Mr.

residing at No.

and having

afflicted with

is an applicant for relief at the N. Y. Orthopædic Dispensary.

Will your Society kindly investigate the pecuniary condition of Mr. _____'s family, and report upon the following questions :

I. Is Mr. _____ a proper subject for Dispensary relief, and a deserving person ?

Answer :

II. Can the family afford to pay for private treatment ?

Answer :

III. The apparatus needed by the patient costs the Institution \$ _____. Can the family afford to pay this amount ?

Answer :

IV. Can they afford to pay *anything* for the apparatus ?

Answer :

V. Do the circumstances and condition of the family indicate that the patient would receive proper care at home ?

Answer :

Please fill in answers in above blank spaces, and return, as per inclosed addressed envelope.

Yours very respectfully,

NEWTON M. SHAFFER, M. D.,
Attending Surgeon in Charge.

In almost every instance a reply is received in twenty-four or thirty-six hours, and, as the patients all have chronic affections, and as they must all wait for the apparatus specially made for them, the delay results in no harm.

The reply, or a document of similar tenor, based upon a knowledge of the patient and his condition, is placed on file in a book kept for that purpose by the surgeon examining the patient, and is the *surgeon's voucher for the admission of the patient*. This book is placed before the trustees each month, and is duly inspected by them.

The scope of the inquiries, as noted, is a broad one. We not only decline to receive those who are able to pay, but also those *who can not receive proper care at home*. Experience has proved that the latter class abuse the dispensary privileges, and that efforts on their behalf result in failure. They are subjects for hospital care, and are placed, so far as our facilities permit, on the free beds in the wards of the institution. If proper care can be extended to the patient, apparatus is supplied, if necessary, and, after investigation, *free of cost*.

In addition to this system of investigation, the Orthopædic Dispensary has a paid system of out-door medical attendance, and last year alone 147 different patients were thus visited over 2,000 times.

The result is extremely satisfactory. We know, as medical attendants, that we are relieving the poor, and thus, in reality and not in semblance alone, make the institution a *true medical charity*.

I am yours truly,

NEWTON M. SHAFFER.

Proceedings of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The seventy-ninth annual meeting was held at Albany, on Tuesday, Wednesday, and Thursday, February 5, 6, and 7, 1884, the President, Dr. ALEXANDER HUTCHINS, of Brooklyn, Kings County, in the chair.

Tuesday.—Morning Session.

The meeting was opened with prayer by the Rev. Dr. HENRY M. KING.

The President then read his INAUGURAL ADDRESS. He suggested that a change be made in details of meetings, so that the President could appoint the Business Committee, and, in conjunction with them, could arrange for the order in which papers should be presented before the commencement of the annual session. Also that queries should be propounded for discussion and prizes offered for the best solution of them. It was desirable that the Governor of the State should act from time to time in the interests of sanitation. Thirty-four orders of this nature had been issued by him already. A tribute was paid to the memory of the late Dr. Elisba Harris, the Secretary of the State Board of Health. The necessity of securing a fire-proof building for the preservation of the Library of the Surgeon-General's Office and the Army Medical Museum was urged. At the last meeting two permanent members had been elected in excess of the number authorized by the by-laws, but certificates of election had been withheld from them by the President. The society had suffered a great loss by the death of Dr. Jacob S. Mosher. It was desirable to establish a supervision of the hospital-training of nurses. The society would do well to make an appropriation of money to sustain the "Index Mediens." The course of certain county societies in admitting to active membership persons not resident in the county was condemned, and it was recommended that such persons be elected only to honorary membership. More caution was enjoined on censors in issuing certificates to poor students, and it was advised that cases be presented to this society before final action. Any scheme for fully endowed colleges to be independent of fees for tuition, however desirable it might seem, was doubtless chimerical. The legislation now proposed to be recommended he condemned as bad, in that it repeated the action of the colleges in granting diplomas, requiring the practitioner to undergo a second examination. All matters which interested the profession should either originate in this society or be referred to it. The by-laws of county societies should be in conformity with the laws of the State society. The laws of only sixteen counties had been so framed.

Three proposals affecting the code had been made at the last meeting. It was to be regretted that members felt bitterly in regard to the action of the society concerning the code. A majority of the five thousand regular physicians of the State, as canvassed, were opposed to the present policy of the society, while only about one fifth openly sustained it. The society had taken no measures to ascertain the sentiment of the majority of its members on this question. Conflict of opinions might be turned into harmonious action if time were given. He closed with a glowing tribute to the memory of the late Dr. J. Marion Sims.

COMMITTEES.—The President then appointed Dr. J. W. MOORE, of Cohoes, Dr. A. M. PHELPS, of Chateaugay, and Dr. J. H. HUNT, of Brooklyn, the *Business Committee*; and Dr. J. N. GOFF, of Cazenovia, Dr. JAMES CHAPMAN, of Medina, and Dr. P. R. H. SAWYER, of Belford, the *Committee on Credentials*.

After a recess of ten minutes, Dr. S. B. WARD, on behalf of the Committee of Arrangements, announced the hours for meeting, etc.

COMMUNICATIONS FROM COUNTY SOCIETIES.—On the call of counties, a report was read from the Albany County Society favoring the passage of the bill for the regulation of the profession now pending in the Legislature. On motion of Dr. H. C. PIERCE, of New York, the subject was made a special order for the Wednesday morning session.

The New York County Society presented a communication recommending an amendment in the by-laws, which was referred to the Committee on By-Laws. It also presented memorials of the late Dr. J. L. Banks and the late Dr. J. M. Sims.

The Ontario County Society presented a resolution opposing the new code, which, together with all matters relating to the code, was made the special order for the evening session.

The Washington County Society presented a resolution opposing the new code, and favoring its repeal by the State society as the necessary condition of securing representation in the American Medical Association, with the recommendation that any modification of the old code that was thought desirable be sought for in the American Medical Association.

THE ARMY MEDICAL MUSEUM AND THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE.—Dr. A. JACOBI, of New York, offered a resolution, which was adopted, urging on Congress the importance of erecting a fire-proof building for the conservation of the national medical library and museum; also the completion of the catalogue, and the replenishing of the library. Ordered that a copy of the resolution be forwarded to Washington, to the chairman of the Committee on Public Grounds.

THE LATE DR. J. MARION SIMS.—Dr. S. O. VAN DER POEL, of New York, presented a eulogium of Dr. Sims, and solicited contributions to the fund now being raised to provide a suitable memorial.

Dr. W. C. WEY, of Elmira, moved that a committee of three be appointed on the President's address. Carried.

THE REPORT OF THE COMMITTEE ON PRIZE ESSAYS was read by Dr. T. F. ROCHESTER, of Buffalo.

The President announced the following COMMITTEE ON THE INAUGURAL ADDRESS: Dr. EDWIN HUTCHINSON, of Utica, Dr. G. J. FISHER, of Sing Sing, and Dr. DAVID WEBSTER, of New York.

Dr. PIFFARD proposed an AMENDMENT TO THE BY-LAWS to the effect that the Business Committee should not provide for the reading of papers by persons who were not members of the society when members had papers to present. He said he would not enforce the new rule till persons already appointed to read papers had been heard. Lost.

DOUBLE HARE-LIP.—A paper with this title was read by Dr. J. P. CREVELING, of Auburn, in which an account was given of a complicated and interesting case.

TWO UNUSUAL CASES IN OBSTETRICAL PRACTICE.—Dr. W. C. WEY, of Elmira, read a paper with this title, in which the first case related was one of concealed ante-partum hemorrhage with some uncommon features, the effusion being thought to have been situated wholly behind, so that the physical appearances of the uterine swelling were not such as are ordinarily met with. The second case was one that possessed many of the phenomena of rupture of the uterus, but in which, nevertheless, the author did not feel warranted in a positive diagnosis.

The paper was discussed by Dr. F. A. CASTLE, of New York. THE SUMMER DIARRHŒA OF INFANTS.—Dr. DAVID LITTLE, of Rochester, read an interesting paper in which he dwelt particularly on the etiology of the affection, more especially with regard to errors of diet. In the author's experience, over-feeding and deprivation of water were answerable for a great proportion of infantile deaths from summer diarrhœa. In an institution of which he had charge, and in which the mortality from diarrhœal diseases had previously been large during the summer, the following plan had been followed the past season: Orders were given that the infants should be fed only once in three hours, but that they should be allowed plenty of water. Instead of once in three hours, they were fed only three times a day, the matron having misunderstood his directions (an error that was not discovered until the end of the summer), and not a single death took place, and there were but two or three cases of severe diarrhœa.

The paper was discussed by Dr. G. H. WOODWARD, of Big Flats, Dr. F. A. CASTLE, of New York, and Dr. W. S. ELY, of Rochester.

CANALIZATION AS APPLIED TO AMPUTATION OF THE FEMALE BREAST, TO INSURE PRIMARY UNION UNDER ONE DRESSING.—This was the title of a paper by Dr. A. G. GERSTER, of New York, which will be published in full hereafter.

AN OPERATION FOR CORRECTING DEFORMITY OF THE AURICLE.—Dr. O. D. POMEROY, of New York, read a paper describing an operation for deformity of the auricle consequent upon arrest of development, and remarked that, in his experience, such deformities were not usually accompanied by arrested development in other parts of the body.

Dr. ARTHUR MATTHEWSON, of Brooklyn, related a case bearing upon some points that Dr. Pomeroy had touched upon.

Dr. JACOBI explained the fact that these malformations of the ear were not usually associated with other results of arrest of development by the early period of fetal life at which the auricle was formed.

POISONING BY POTASSIUM CHLORATE was the title of the next paper, by Dr. GEORGE B. FOWLER, of New York, relating a case in which a patient who took six hundred grains in a day passed urine in small quantity and of a sp. gr. of 1.055. Stress was laid on the irritating effects of the salt, and on the necessity of caution in its use.

Dr. JACOBI, Dr. CASTLE, Dr. DANIEL LEWIS, of New York, and Dr. S. SHERWELL, of Brooklyn, took part in the discussion.

Tuesday.—Afternoon Session.

Dr. JOHN G. CURTIS, of New York, presented a REPORT FROM THE COMMITTEE ON EXPERIMENTAL MEDICINE, urging the importance of experiments on living animals. The report was adopted.

THE COMMITTEE ON NOMINATIONS was announced as follows: From the Society at Large, E. H. PARKER, of Poughkeepsie; First Senatorial District, LAURENCE JOHNSON; second district GEORGE C. SMITH; third district, F. C. CURTIS; fourth district L. E. FELTON; fifth district, H. G. DU BOIS; sixth district, W. W. CRANDALL; seventh district, DARWIN COLVIN; eighth district, JOHN O. ROE.

THE PROPOSED STATE MEDICAL FACULTY.—Dr. W. C. WEY, of Elmira, offered the following:

Resolved, That "A Bill to establish the Medical Faculty of the University of New York" be and hereby is referred to the Committee on Legislation, with instructions to report to the society to-morrow, Wednesday, morning, when the order for the report of said committee is reached. Seconded by Dr. Agnew.

The Business Committee reported obituary notices of Dr. James Lenox Banks, by Dr. F. A. Burrall; of Dr. J. Marion Sims, by Dr. Wesley M. Carpenter; and of Dr. James Rushmore Wood, by Dr. Frederic S. Dennis. They were referred to the Publishing Committee.

Dr. POWELL, of Toronto, was introduced as an invited guest, and made a short address, extolling the merits of the Dominion Medical Practice Act.

Dr. EDWIN HUTCHINSON read a REPORT FROM THE COMMITTEE ON THE PRESIDENT'S ADDRESS. It particularly commended the first suggestion, and offered the following resolutions:

Resolved, That hereafter the President shall appoint the Business Committee in advance of the annual meeting and at as early a period as practicable, for the purpose of securing scientific work for the next annual session.

Resolved, That the President shall hereafter be a member of the Business Committee *ex officio*.

Resolved, That, should a vacancy occur in any committee of this society, the President is hereby authorized to fill such vacancy.

Dr. W. M. CARPENTER, of New-York, moved that the reso-

lutions be referred to the Committee on By-Laws, with the recommendation that they be adopted, and reported back to the society for action. Carried.

An obituary notice of Dr. Morgan Snyder, of Fort Plain, by Dr. Alexander Ayres, was read by title.

A resolution was offered that there should be a Committee on Necrology, consisting of three members. Referred to the Committee on By-Laws.

THE ESTABLISHMENT OF HOSPITALS IN SMALL CITIES.—Dr. E. H. PARKER, of Poughkeepsie, read a paper in which he described the organization and management of a very successful hospital in that city.

A NEW METHOD OF PARTIAL EXTIRPATION OF THE CANCEROUS UTERUS.—Dr. ELY VAN DE WARKER, of Syracuse, read a paper reviewing the various methods of operation, and described his own plan of removing the greater part of the thickness of the organ in the form of a slough produced by the action of a strong solution of chloride of zinc. The results were better, he thought, than those that followed the use of the knife. The late Dr. Sims had taught us how to apply caustics with precision.

THE VALUE OF ELECTRICITY IN DIAGNOSIS.—Dr. L. E. FETTON, of Potsdam, read a paper in which he described the details of the proper use of electricity for diagnostic purposes.

CONGENITAL LIPOMA.—Dr. JACOBI alluded to the rarity of congenital lipoma in general, and to its comparative rarity in various parts of the body. He related cases that he had met with, and spoke of the complications that had been found.

ORBITAL CELLULITIS.—This was the title of a paper by Dr. THOMAS R. POOLEY, of New York, which will be published in full hereafter.

A PLEA FOR THE PHARMACOPEIA was the title of a paper by Dr. LAURENCE JOHNSON, of New York, in which he urged general adherence to the use of pharmacopoeial preparations, and deprecated the tendency to use compounds devised by pharmacists.

The paper was discussed by Dr. JACOBI, Dr. W. F. MITTENDORF, and Dr. CASTLE, of New York.

OPERATIONS FOR CLOSURE OF THE HARD AND SOFT PALATE.—Dr. A. VANDERVEER, of Albany, read a paper embodying the views to which his experience had led him in regard to operations for these deformities. He had had the best results with Ferguson's operation, and urged its performance in infancy. In the case of adults an operation was seldom followed by material improvement of the voice, but, even with them, the regurgitation of fluids through the nostrils was prevented more certainly than by the use of obturators. Free dissection was the important point in the operation.

Dr. GEESTER and Dr. POWELL, of Toronto (present by invitation), took part in the discussion.

The following papers were read by title: DYSENTERY; ITS TREATMENT BY DILATATION, by Dr. W. W. POTTER, of Buffalo; TWO CASES OF RUPTURE OF THE HEART, by Dr. F. H. SQUIRE, of Elmira; A BIOGRAPHICAL SKETCH OF THE LATE JAMES RUSMORE WOOD, M.D., LL.D., by Dr. FREDERIO S. DENNIS, of New York; A BIOGRAPHICAL SKETCH OF THE LATE DR. G. W. BRADFORD, by Dr. C. GREEN, of Housier; A BIOGRAPHICAL SKETCH OF THE LATE DR. J. FOSTER JENKINS, by Dr. G. J. FISHER, of Sing Sing; THE MEDICAL SOCIETY OF THE STATE OF NEW YORK IN ITS RELATION TO SANITARY SCIENCE AND THE PUBLIC HEALTH, by the late Dr. ELISHA HARRIS, of Albany; A BIOGRAPHICAL SKETCH OF THE LATE DR. J. S. BAILEY, by Dr. F. C. CUESTIS, of Albany.

A CASE OF SYMPATHETIC SEROUS IRITIS, WITH REMARKS.—Dr. DAVID WEBSTER read a paper with this title, which was discussed by Dr. MITTENDORF.

HORSE-HAIR DRAINAGE.—Dr. DANIEL LEWIS, of New York,

read a paper in which he expressed himself as convinced of the excellent qualities of horse-hair for sutures.

Dr. E. M. MOORE, of Rochester, coincided with the views put forward by Dr. Lewis.

The following papers were read by title: SPONTANEOUS PYÆMIA, by Dr. J. B. TODD, of Parish; THE CARE AND PRESERVATION OF MEDICAL PAMPHLETS, by Dr. G. J. FISHER, of Sing Sing; STRANGULATED HERNIA, WITH A REPORT OF FIVE CASES OF OPERATION, by Dr. J. CHAPMAN, of Medina; NOTES ON THE TREATMENT OF DERANGEMENTS OF THE DIGESTIVE ORGANS, by Dr. F. A. CASTLE, of New York; HAY FEVER, by Dr. J. O. ROE, of Rochester; PRIMARY DRAINAGE AND SECONDARY SUTURE, by Dr. GEORGE B. FOWLER, of New York.

HOUSE SANITATION AS IT IS, AND AS IT SHOULD BE.—Dr. W. F. SHEEHAN, of Rochester, read a paper with this title. It was discussed by Dr. A. N. BELL, of Brooklyn.

THE FUNDAMENTAL PRINCIPLES OF MECHANICAL THERAPY IN HIP DISEASE was the title of a paper read by Dr. MILTON JOSEPH ROBERTS, of New York, who treated the subject from the physiological standpoint. The paper was discussed by Dr. FOWLER.

SYNOVITIS OF THE KNEE JOINT.—Dr. A. M. PHELPS, of Chateaugay, read a paper on this subject, and showed a number of mechanical appliances of his own devising.

MORBID SOMNOLENCE was the title of a paper read by Dr. C. L. DANA, of New York.

Tuesday.—Evening Session.

THE CODE OF ETHICS.—Dr. H. G. PIFFARD, of New York, moved that the communication from Ontario, which was laid on the table in the morning, be now taken from the table and read. Carried. The communication was then read by the Secretary, being an appeal for the restoration of the National Code.

Dr. Piffard moved that the communication be received and placed on file. Carried.

Dr. Piffard offered the following: *Resolved*, That the Secretary be instructed to inform the Medical Society of Ontario County that any by-law adopted by that society which was not approved by this society would have no legal force.

Dr. A. G. CRITTENDEN, of Clifton Springs, explained that the resolutions adopted by Ontario County were not of the nature of a by-law, but were a remonstrance.

Dr. Piffard's resolution was carried.

Dr. F. J. BAKER, of Lockport, presented a communication from Niagara County similar to that from Ontario County. On motion, it was received and ordered to be entered upon the minutes.

After a pause, Dr. F. R. STURGIS, of New York, inquired if there was any special business before the house. The President replied that there was a special topic designated for this evening. After further silence, Dr. PIFFARD moved that, if there was no business of the character which had been made the special order, the meeting now proceed to the reading of papers under direction of the Business Committee.

At Dr. E. M. MOORE's request, the motion was withdrawn, and the resolutions offered last year by Dr. DIDAMA were read by the Secretary.

Dr. MOORE moved the adoption of these resolutions.

[The purport of these resolutions was to repeal the new code and restore the old code. The full text of the resolutions was given in our issue of February 17, 1883, p. 191.]

Dr. T. F. ROCHESTER, of Buffalo, seconded the motion, and said that Dr. Didama would probably soon be present, and would desire to speak in favor of his own resolution. Remonstrances against the new code from county societies, such as had been received here to-night, showed the feeling of the majority

of the profession in the State, and should not be received with jeers and tabled. The alteration of the by-laws in 1882 was made when the profession were not prepared for it, and when it was not expected that the topic would be definitively settled. The large attendance now present was for the purpose of saving the society from the disintegration which awaited it if the new code were to stand.

Dr. H. D. DIDAMA, of Syracuse, then came in, and was given the floor. He wished to make a plea in the interest of harmony and fairness, and he had reduced it to writing. It could be shown in their own handwriting that less than one third of the members of the State society, and less than one fifth of the profession in the State, favored the new code. And the profession in the State and out of the State believed that the old code had been unjustly snatched away, and that the new code had been unfairly established.

Dr. D. B. SR. JOHN ROOSA, of New York: Two new arguments have been presented to-night by those who favor the resolutions of Dr. Didama. One argument is based on a threat that under certain circumstances a new society will be formed. We are told that, unless we yield to the minority, they will go out from us and form an irregular society. They come to us with an olive-branch in one hand and a hatchet in the other. The minority are for harmony, provided the majority do exactly as they say. The other argument, the notion that the adherents to the old code are in a majority in the State, is as delusive as the similar view as to their numbers in New York City has been proved to be. Other States will soon follow in the line after New York, and leave the American Medical Association.

Dr. A. JACOB, of New York, moved the previous question. This was withdrawn to allow Dr. E. M. Moore, of Rochester, the privilege of the floor.

Dr. MOORE said that he was detained as a witness last year, and had had no opportunity to express himself on this question. After reading a long editorial article from the "Journal of the American Medical Association," he said that when we severed our relations with the association we violated the principles of comity and courtesy. In 1882 he urged a reference of the code question to the American Medical Association, in order to preserve our harmonious relations with all other societies.

Dr. JACOB again moved the previous question, and the yeas and nays were called, with the following result, the President having ruled that a two-thirds affirmative vote was required for the passage of the resolutions:

AYES.—E. Ames, J. N. Arnold, Alex. Ayres, J. H. Abell, J. G. Adams, C. S. Allen, Geo. Abbott, J. C. Boyd, R. B. Bon-tecoo, F. J. Baker, Guy C. Bailey, M. H. Burton, C. G. Bacon, Wm. C. Bailly, Wilbur H. Booth, J. E. Beard, J. Chapman, A. G. Crittenden, D. Colvin, Wm. Chase, John Cronyn, J. M. Crawe, A. Churchill, A. M. Campbell, W. S. Cooper, J. R. Cotes, J. E. Casey, G. W. Cooke, I. G. Collins, A. J. Dallas, L. C. Dodge, H. D. Didama, J. Davidson, H. G. Du Bois, J. C. Dalton, H. J. Dean, J. C. Edson, J. W. Eddy, G. W. Earle, E. F. Edgerly, E. D. Ferguson, Wm. Fitch, Austin Flint, A. Flint, Jr., J. W. Grosvenor, Wm. Gillis, C. S. Grant, J. C. Green, F. S. Green, C. Green, D. Guernsey, J. W. S. Gouley, Alex. Hutchins, A. D. Head, J. H. Hunt, E. A. Houghton, J. H. Hinton, Fred. Hyde, B. L. Hovey, S. T. Hubbard, N. C. Huested, C. M. Johnson, T. M. Johnson, H. O. Jewett, A. C. Jackson, C. Jewett, Frank Kenyon, Henry Lapp, W. E. Lauderdale, Jr., E. M. Lyon, D. N. Lee, J. K. Loeming, E. McKenzie, J. W. Moore, E. M. Moore, Robt. Newman, C. E. Nichols, Israel Parsons, T. E. Parkman, C. G. Pomeroy, H. C. Palmer, T. B. Reynolds, Wm. Ring, T. F. Rochester, J. P. Sharer, T. D. Stony, T. H. Squire, Z. Rousseau, A. W. Suiter, S. Sherwell, G. C. Smith, B. G. Streeter, E. R. Squibb, B. A. Segur, W. P. Seymour, H. Slack, Conant Sawyer,

J. B. Todd, M. W. Townsend, R. Thomson, E. Vanderwarker, C. S. Wood, R. H. Ward, Thos. Wilson, R. M. Wykoff.—*Total, 105.*

NAYS.—J. Q. Adams, W. T. Alexander, C. R. Agnew, E. Allison, M. J. Baker, E. H. Bridges, W. R. Birdsall, F. D. Beebe, A. J. Browne, E. Beach, N. H. Ballou, A. C. Benedict, W. H. Bailey, C. C. Bartholomew, W. M. Carpenter, H. S. Crandall, F. A. Castle, W. W. Crandall, W. B. Chase, J. P. Creveling, J. R. Cooper, C. Carey, W. H. Craig, F. C. Curtis, D. F. Dayton, C. L. Dana, F. S. Drake, T. A. Emmet, W. S. Ely, R. Fraser, R. M. Fuller, L. E. Felton, G. R. Fowler, F. P. Foster, G. J. Fisher, J. D. Featherstonhaugh, S. H. Freeman, G. H. Fox, A. G. Gerster, I. N. Goff, V. P. Gibney, P. R. Furbeck, Emil Gruening, J. W. Howe, C. R. Heaton, A. Hadden, H. R. Hopkins, T. Helme, James C. Hutchison, L. Howe, Edwin Hutchinson, B. L. Holt, E. Herrick, L. Johnson, W. H. Johnson, H. Jewett, William Hailes, A. Jacobi, S. E. Jones, A. M. Jacobus, D. Lewis, F. S. Low, A. L. Loomis, C. M. Leffer, D. Little, T. Lothrop, A. V. B. Lockrow, J. Lewi, A. Mandeville, H. March, G. G. Munro, A. Mathewson, J. Moffat, L. McLean, W. F. Mitten-dorf, B. A. Mynderse, H. H. Nye, C. A. Nicholson, J. D. Potter, T. R. Pooley, W. W. Potter, O. D. Pomeroy, A. M. Phelps, E. L. Partridge, R. W. Pease, M. Perkins, J. S. Prout, C. H. Porter, H. G. Piffard, E. H. Parker, P. V. S. Prun, J. O. Roe, D. B. St. J. Roosa, B. G. Senten, G. Seymour, A. S. Seebor, H. G. P. Spencer, F. R. Sturgis, W. Manlius Smith, F. H. Stewart, J. C. Shaw, C. L. Stiles, E. V. Stoddard, P. R. H. Sawyer, B. F. Sherman, N. L. Snow, N. F. Sheehan, G. F. Shradly, William Taylor, R. K. Tuthill, S. O. Van der Poel, E. Van Slyke, A. Vanderveer, S. B. Ward, W. Woodward, J. H. Wheeler, C. E. Willard, H. R. Winter, J. S. Warren, F. M. Weld, D. Webster, W. C. Wey, C. E. Whitbeck, W. G. Wylie.—*Total, 124.*

The resolutions were therefore declared lost.

THE "DECLARATORY RESOLUTION."—When the vote had been declared, Dr. ROOSA said: During the progress of this discussion it has been said that there were a large number of men who voted for the old code who would much rather have voted for the code I offered three years ago. I wish to redeem the pledge I then made, and give them the opportunity. If there is any feeling in the minority that they prefer such a resolution as this to the new code which has remained the law of the State society, I am glad to join them; but, if there is no such desire on the part of this minority, I have no wish to ask my fellows to reopen this question; and, with this explanation, I will second the motion of any member of the minority who prefers this resolution, and attempt to get a tentative vote. I claim your indulgence, for I am under an obligation to renew this motion. I consider that I have complied with this obligation.

Dr. JACOB moved that Dr. Roosa's resolution be now put.

By request, Dr. ROOSA read his resolution. [See the "New York Medical Journal" for February 17, 1883, p. 189.] Dr. Roosa added that the second clause of the resolution was withdrawn, as it had been shown to be unconstitutional.

Dr. JACOB moved that this resolution take the place of the new code.

Dr. C. R. AGNEW, of New York, advocated Dr. Jacobi's motion.

After some discursive talk by various members, Dr. JACOB withdrew his motion.

Wednesday.—Morning Session.

The session was opened with prayer by the Rev. WALTER D. NICHOLAS.

After the reading of the minutes, Dr. N. S. BABBITT, of North Adams, Mass., was introduced, and made a brief address.

THE TREASURER'S REPORT.—Dr. CHARLES H. PORTER, of Al-

bany, the Treasurer, read his annual report. The receipts were \$3,179.17, the expenses \$2,272.11, and the balance in the treasury is \$1,162.92, against \$555.90 last year. The report was referred to an auditing committee consisting of Dr. Jacobi and Dr. Bull.

THE PRIZE FUND.—Dr. PORTER read the report of the Committee on the Merritt H. Cash Prize Fund; also that of the committee appointed to secure new quarters for the society, to the effect that there was a prospect of securing better quarters next year.

THE VOLUMES OF TRANSACTIONS.—Dr. F. C. CURTIS, of Albany, read the report of the Committee on Publication. There was but little demand for the volumes that were out of print, and the committee recommended that they be not reprinted. Adopted, and the committee discharged.

Dr. W. C. WEX read the report of the Committee on By-Laws, and presented resolutions, which were adopted. The resolutions approved the by-laws of the following county societies: Saratoga, Ulster, Yates, Tioga, Columbia, Cayuga, Rensselaer, Oneida, Clinton, Putnam, St. Lawrence, Washington, Schoenectady, Tompkins, and Essex. Amendments to the by-laws of the county societies of New York and Albany were approved.

THE PRIZE ESSAYS.—Dr. W. S. ELY called attention to the fact that the report of the Committee on Prize Essays, presented yesterday, was signed by Dr. Moore, who was not a member of that committee, and lacked the signature of Dr. W. W. Potter, one of the members of the committee. The report was referred back to the committee.

Dr. JACOBI presented the REPORT OF THE COMMITTEE ON THE PREVENTION OF CRUELTY TO CHILDREN, embodying a resolution that this society appoint a committee to co-operate with the Society for the Prevention of Cruelty to Children.

Dr. PIFFARD offered a resolution that the Secretary have printed a sufficient number of copies of the proceedings of this society to provide every member of the county societies affiliated with it with a copy. Carried.

Dr. E. W. STODDARD, of Rochester, read a REPORT OF THE COMMITTEE ON HYGIENE, which was accepted.

THE STATE EXAMINING BOARD.—The special order was then taken up, namely, the acts to establish a State examining board, now before the Legislature.

Dr. F. R. STURGIS, of New York, read the report of the Committee on Legislation, and presented the bill now pending in the Assembly (No. 120). The committee further reported that the Attorney-General of the State had taken action during the year against two medical colleges incorporated under the act of 1818, and had closed the colleges, the court holding that that act was not applicable to the incorporation of such colleges.

Dr. PIFFARD moved that the report be received.

Dr. H. R. HOPKINS, of Buffalo, offered a resolution favoring the bill recommended by the committee.

Dr. AGNEW moved to lay the report of the committee on the table.

Dr. ROOSA rose to the point of order that the motion to table was made too late. The point of order was sustained.

Dr. PIFFARD's motion was carried.

Dr. AGNEW moved to refer the matter back to the committee, with instructions to report another bill (known as the "Medical College Bill").

Dr. ROOSA thought it would be putting a slight on the committee to require them to report a bill they did not approve of.

Dr. PIFFARD raised the point of order that all matters must be referred to the committee, "which shall report," etc. (reading from the by-laws).

After discussion, Dr. ROOSA moved an amendment that the committee should not recommend the bill.

Dr. PIFFARD raised the point of order that it was improper to instruct the committee how they should report.

Dr. AGNEW's motion was carried, and the committee handed in a copy of the bill, which was received and entered on the minutes. The chairman of the committee stated that the committee disapproved of the bill.

Dr. HOPKINS offered a resolution that the report of the committee be accepted, and that the committee be instructed to press this bill before the Legislature. He made an address in support of his resolution.

Dr. PIFFARD moved that the resolution be amended so as to designate the bill favorably reported by the committee as the one indorsed by this society, which amendment was accepted.

Dr. A. L. LOOMIS, of New York, made an address favoring the last bill reported. He thought the profession should be united before presenting any bill to the Legislature. The first point he noted was in the first section of the two acts—the manner in which the board was to be composed. The great point of difference between the bills was in the powers of the examining board; the one made them supervisory, the other absolute. In the bill he favored there was a provision for suppressing bogus colleges without legislation. It also guaranteed a high standard of attainments in graduates. In the other bill, it was proposed to give absolute power to an irresponsible board, the composition and character of which could not be foreseen. Again, England had tried taking examining boards from a non-teaching body, and had found it a failure. "Just so soon," he continued, "as you put the appointing power into the hands of a power that is not a professional power, you are in danger." (Applause.)

The next question was as to the compensation of these examiners. A good man could not be had for the sum of \$700 a year, which was about what members of this board would average. It would take two months to examine three hundred men. The colleges of the State are already doing good work in examinations. He objected to this bill also because it gave the power of adding to the curriculum of the colleges.

Dr. HOPKINS having raised the point of order that no such provision was contained in the bill, Dr. Loomis called attention to such a provision in section 4: "And such other branches," etc. As for the argument that the profession was overcrowded, "Gentlemen, do you propose to establish a trades-union?" (Applause.) There should be a union between the profession and the college.

Dr. ROOSA said he had had great opportunities to know something of medical colleges, and he would say that the medical colleges of the State reflected the greatest honor upon our profession. Most of the advances of the past twenty years had come through the medical colleges. He thought the real object of the second bill was to defeat any bill. He had had assurances that, if this society should agree on any bill, there was a good prospect of its being presented to the Governor. It was stated before the Legislature that the bill had never been discussed before this society.

Dr. AGNEW and Dr. PIFFARD both corrected this statement.

Dr. ROOSA also insisted that this society had, on previous occasions, indicated preferences for a proper bill. Any bill containing provisions such as those in sections 7 and 8 was a gigantic farce. He objected to any bill that proposes to take the examining board down to New York on a tea-drinking party with the faculties there—that was unduly influencing the jury. He was willing to agree to any bill that did not enslave the measure. The license to practice should be obtained from the State.

Dr. PIFFARD quoted at length from an article by himself, and made an address in favor of the second bill reported by the committee. He proceeded with an elaborate historical sketch of the movement under discussion. He specially opposed the formation of boards embodying separate sects. He repudiated the imputation that the members of this society practiced any "system" of medicine. He criticised various details of the committee's bill—such as the prohibition of graduates affixing the letters M. D. to their names unless licensed, which would make it a misdemeanor for the most eminent physician in Philadelphia (mentioning Dr. Gross) to register his name and title at any hotel in New York where he might be staying; the requirement that copies of all diplomas should be kept in the county clerk's office; the stringent language of section 12, which would interdict the practice of dentistry by any but a registered physician, etc.—and expressed surprise that such a bill should have been drawn by any person professing to be a lawyer. On the other hand, he pointed out several commendable features of the second bill, and concluded with the recommendation that both bills should be referred to some committee, for the purpose of harmonizing them and correcting objectionable features.

Dr. JACOBI thought that neither bill was perfect, and both might well be amended. We needed a bill that was both effective and constitutional. The interest of the public in this matter was much larger than that of the colleges, and, if we did not soon prepare a bill, the Legislature would pass one of its own accord. He moved that the matter be taken up again at the afternoon session, with the determination to come to a final vote before adjournment.

Dr. AGNEW offered a substitute to the effect that the report be recommended to the committee, with power, and that five additional members be added to the committee. An amendment was carried stating the hour as three o'clock, and Dr. Jacobi's motion was carried.

Wednesday.—Afternoon Session.

ADJOURNED DISCUSSION ON THE EXAMINING-BOARD BILLS.—Dr. J. W. HOWE, of New York, remarked that the Society of the County of New York had declined to not approve the committee's bill, for the reason that it had not been carefully prepared and considered. We should consult the teachers before we took action on any bill. The proposed board was objectionable because it excluded teachers. This society could exercise a better supervision than any board. He offered this amendment: that a committee of this society be appointed to draft a plan for an examining commission to attend the college examinations in behalf of the society.

Dr. J. C. DALTON, of New York, seconded the amendment and supported the measure, because this can not be properly effected by legislation, and because the control ought to be kept within this society. These bills would work harm: one bill disconnected the degree of M. D. from the right to practice. This would not purify the profession. If we took away from the degree of M. D. the right to practice, we should simply relieve the colleges of their present responsibility. Such a board as was proposed could not be in session one day without showing that the eclectic held the balance of power. A law once passed was hard to amend, and no law ever operated quite according to previous expectation.

After a running discussion, both the original resolution and Dr. Howe's amendment were laid on the table.

Dr. HOPKINS offered a resolution declaring that the society was in sympathy with the effort to establish a State board of examiners.

Dr. VAN DER POEL moved that the matter be referred to a committee consisting of the present Committee on Legislation

(Dr. Sturgis and Dr. Vanderveer) and Dr. A. L. Loomis, Dr. J. G. Curtis, Dr. Austin Flint, Jr., Dr. Maurice Perkins, and Dr. E. M. Moore, with power.

Dr. HOPKINS opposed the amendment on the ground that it took the matter away from the regular Committee on Legislation.

Dr. JACOBI wished to hear from the gentlemen from the interior of the State, who had hitherto refrained from announcing their opinions.

Dr. GEORGE C. MOORE, of Oneida, responded that, in his opinion, it was all wrong to push a measure of this kind through in so short a time, without consulting all the members of the fraternity throughout the State. The committee should not have full power to act, but should simply consider measures and report.

Dr. PIFFARD ordered an amendment to Dr. Hopkins's resolution, that the matter be referred to a committee, consisting of the Committee on Legislation, and Dr. Loomis, Dr. Vanderveer, and Dr. J. G. Curtis.

Dr. LOOMIS favored an examining board, and promised to have a bill here next year which every member would approve of.

Dr. WEY favored deferring this business for one year.

Dr. ROCHESTER favored a State board, but thought we should not act in a hurry.

Dr. PIFFARD accepted a suggestion that the committee communicate with the county societies, as an amendment to his motion. The motion, as amended, was carried. The President appointed, as a committee to co-operate with the Society for the Prevention of Cruelty to Children, Dr. Jacobi, Dr. Van der Poel, and Dr. Loomis.

Dr. ROCHESTER, from the COMMITTEE ON PRIZE ESSAYS, explained that he had sent the report of the committee to Dr. W. S. Ely. He had supposed that Dr. Moore was a member of the committee, and so had Dr. Moore himself. He then presented as the majority report of the committee, the same report read yesterday.

Dr. POTTER read a minority report, signed by himself, characterizing the essay on "Tubercles of the Breast" as unworthy of the prize, for the reason that it was not largely original, but consisted almost entirely of extracts from other authors, which work did not answer the requirements.

Dr. VAN DER POEL moved that the minority report be adopted. Carried.

The Business Committee presented an obituary of Dr. J. G. Snell, of Palatine Bridge.

The Committee on Hygiene presented a report.

Dr. WEY reported from the Committee on By-Laws, favoring the approval of certain amendments to the by-laws of the Albany County Society; opposing the creation of a committee on necrology; and presenting a resolution that the Treasurer and Secretary be authorized to act as a temporary committee on credentials at the annual meetings until the organization of the meeting. All the recommendations were adopted.

Wednesday.—Evening Session.

THE PRESIDENT'S ANNUAL ADDRESS was delivered. [See p. 141.]

Thursday.—Morning Session.

THE MANAGEMENT OF FACE PRESENTATION.—Dr. E. L. PARTRIDGE, of New York, read a paper on this subject.

ARSENIC AND DIGITALIS IN PHTHISIS.—Dr. JACOBI read a paper recounting his experience in the use of arsenic in certain forms of phthisis. In many cases he had found the drug of signal service, but he had not found it useful in cases that had advanced to the hectic stage.

The second part of the paper dealt with the use of digitalis in forms of pulmonary and other diseases associated with defective cardiac power. The drug was a direct tonic to the heart in all conditions of the organ save that of acute inflammation.

Dr. F. R. S. DRAKE, of New York, had seen benefit result from the use of arsenic in certain cases of phthisis with hectic. In regard to digitalis in pulmonary affections, it was the custom at Bellevue Hospital to give the drug in most cases of pneumonia, particularly of the alcoholic variety.

THE PUBLICATION OF THE PROCEEDINGS.—Dr. W. M. CARPENTER moved that the society have a sufficient number of copies of the proceedings printed, and mailed from the publication office direct to the members of the various county societies, instead of mailing them to the secretaries of the county societies, as proposed by Dr. Piffard in his motion. Carried.

NOMINATIONS FOR THE ENSUING YEAR.—The report of the Committee on Nominations was made and adopted as follows: *President*, B. F. SHERMAN, Ogdensburg; *Vice-President*, P. R. H. SAWYER, Bedford; *Secretary*, W. M. SMITH, Syracuse; *Treasurer*, C. H. PORTER, Albany; *Censors*: (Southern District) F. A. CASTLE, G. H. FOX, DAVID WEBSTER, New York; (Eastern District) E. D. FERGUSON, Troy, N. L. SNOW, Albany, Le Roy McLEAN, Troy; (Middle District) ALONZO CHURCHILL, Utica, J. K. CHAMBERLAIN, Utica, ROBERT FRAZER, Camden; (Western District) T. F. ROCHESTER, Buffalo, B. L. HOVEY, THEODORE DIMON, Auburn; (Medical Department of Syracuse University) J. P. CREVELING, Auburn; *Committee of Arrangements*, S. B. WARD, Albany, W. S. ELY, Rochester, E. L. PARTRIDGE, New York; *Committee on By-Laws*, W. C. WEY, Elmira, ALEXANDER HUTCHINS, Brooklyn, W. M. SMITH, Syracuse; *Committee on Hygiene*, E. V. STODDARD, Rochester, CALEB GREEN, Homer, EDWIN HUTCHINSON, Utica, W. H. BAILEY, Albany, A. N. BELL, Brooklyn, G. J. FISHER, Sing Sing, W. T. SHEEHAN, Rochester; *Committee on Medical Ethics*, A. JACOBI, New York, A. MATTHEWSON, Brooklyn, J. W. WHITEBECK, Rochester; *Committee on Prize Essays*, W. W. POTTER, Buffalo, A. HUTCHINS, Brooklyn, W. S. ELY, Rochester; *Committee on Publication*, W. M. SMITH, Syracuse, C. H. PORTER, Albany, H. D. DIDAMA, Syracuse; *Permanent Members*: (First District) D. LEWIS, A. V. B. LOCKBROW, V. P. GIBNEY, A. McL. HAMILTON, New York, S. SHERWELL, Brooklyn; (Second District) A. HUBNE, Rondout, J. Q. ADAMS, Carmel; (Third District) M. L. BATES, Canaan Four Corners, S. S. CARTWRIGHT, Roxbury; (Fourth District) L. C. DODGE, Rouse's Point, J. E. BURDICK, Johnstown; (Fifth District) H. W. CARPENTER, Oneida; (Sixth District) M. J. BAKER, Hornellsville, M. D. SPENCER, Guilford; (Seventh District) ALFRED MERCER, Syracuse; (Eighth District) C. S. STARR, Rochester, M. S. KITTINGER, Lockport; *Honorary Members*, W. G. BRONSON, Connecticut; *Delegates to the International Medical Congress*, S. O. VAN DER POEL, New York, A. M. PHELPS, Chateaugay, J. O. ROE, Rochester, A. VANDERVEER, Albany, J. P. CREVELING, Auburn, W. H. BAILEY, Albany, A. HUTCHINS, Brooklyn, A. JACOBI, G. F. SHRADE, New York; *Delegates to the Massachusetts Medical Society*, G. C. MONROE, Creary's Mills, G. G. HOPKINS, Brooklyn, H. MARON, Albany; *Delegates to the Connecticut Medical Society*, M. L. BATES, Canaan Four Corners, S. H. FREEMAN, Albany; *Delegates to the Canadian Medical Association*, L. E. FELTON, Potsdam, C. M. WILSON, Gouverneur, C. SAWYER, Au Sable Forks, F. C. CURTIS, Albany, D. V. O'LEARY, Albany; *Delegates to the British Medical Association*, F. BARKER, New York, H. JEWETT, Canandaigua; *Delegates to the Ontario Medical Association*, H. R. HOPKINS, L. HOWE, Buffalo; *Delegates to the Pennsylvania Medical Society*, C. L. STILES, Owego; *Delegates to the Vermont Medical Society*, J. L. LITTLE, New York, J. LEWIS, Albany.

Dr. WARD moved that the thanks of the society be extended

to the New York State Agricultural Society for the use of this room, etc. Carried.

Dr. WM. M. SMITH moved that all papers on the roll, and not read, be read by title and referred to the Committee on Publication. Carried.

Dr. CARPENTER moved a vote of thanks to the President of the society. Carried.

The PRESIDENT responded.

Dr. SHERMAN moved a vote of thanks to the Committee of Arrangements. Carried.

Dr. JACOBI moved a vote of thanks to the Business Committee. Carried.

The meeting then adjourned.

INVITED GUESTS.—During the sessions the following-named physicians were invited to take part in the proceedings as guests: Dr. W. S. TREINAIN, U. S. Army, of Buffalo; Dr. T. P. BAILEY, of Albany; Dr. J. B. STONEHOUSE, of Albany; Dr. F. A. ANDERSON, of Messina; Dr. M. S. KITTINGER, of Lockport; Dr. PETER FALING, of Gosport; Dr. W. W. SEYMOUR, of Troy; Dr. S. S. WALLIAN, of Bloomingdale; Dr. G. P. CLARK, of Syracuse; Dr. ALFRED MERCER, of Syracuse; Dr. S. R. MORROW, of Albany; Dr. M. D. MANN, of Buffalo; Dr. L. A. STIMSON, of New York; Dr. J. S. COOLEY, of Luzerne; Dr. LORENZO HALE, of Albany; Dr. S. G. DELAMATER, of Schenectady; Dr. W. S. LAYMAN, of Schoharie; Dr. H. F. KINGSLEY, of Schoharie; Dr. J. C. HANNAN; Dr. J. A. HALL, of Green Island; Dr. F. TOWNSEND, of Albany; Dr. D. H. COOK, of Albany; Dr. R. H. SABIN, of West Troy; Dr. W. B. SABIN, of West Troy; Dr. A. T. VAN VRANKEN, of West Troy; Dr. ISAAC DEZOUCHÉ, of Fulton County; Dr. G. E. LYON, of West Troy; Dr. W. L. SCHUTTER, of Albany; Dr. E. A. BARTLETT, of Albany; Dr. H. BENDALL, of Albany; Dr. O. D. BALL, of Albany; Dr. W. H. TOWSLEY, of South Richmond; Dr. MAURICE J. LEWIS, of Albany; Dr. T. Z. GIBBS, of Fort Ann; Dr. LEMUEL CROSS; Dr. N. A. POWER, of Toronto; Dr. C. S. MERRILL, of Albany; Dr. F. L. CLASSEN, of Albany; Dr. DAVID FLEISCHMAN, of Albany; Dr. MARY DUBOIS, of Albany; Dr. H. S. CASE, of Albany; Dr. G. L. ULLMAN, of Albany; Dr. J. D. LOMAX, of Troy; Dr. W. M. McLAURY, of New York; Dr. LEWIS BALCH, of Albany; Dr. JOHN THOMPSON, of Albany; Dr. J. F. BARKER, of Albany; Dr. T. W. NELLIS, of Albany; Dr. H. B. ALLEN, of Baldwinsville; Dr. W. J. NELLIS, of Albany; Dr. A. M. SMITH, of Williamstown, Mass.; Dr. N. S. BABBITT, of North Adams, Mass.; Dr. HENRY E. ALLISON, of Waterloo; Dr. M. J. ROBERTS, of New York; Dr. T. C. WALLACE, of Cambridge; Dr. WILLIAM STEVENS, of New York; Dr. HARRIET A. WOODWARD, of Albany; Dr. L. ROUCHEL, of Albany; Dr. B. U. STEENBERG, of Albany; Dr. R. D. CLARK, of Albany; Dr. J. D. McALLISTER, of Albany; Dr. J. P. BOYD, of Albany; Dr. G. H. NEWCOMB, of Albany; Dr. R. H. PLUMMER, of San Francisco; Dr. C. DEVOL, of Albany; Dr. D. C. CASE, of Slingerlands; Dr. ANTHONY TEN EYCK, of Defriestville; Dr. W. H. ROBB, of Amsterdam; Dr. P. J. KEEGAN, of Albany; Dr. A. FOWLER, of Albany; Dr. AGNES SEELYE, of Bath, Vice-President of Steuben County Medical Society.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

THE PRESIDENT'S ANNUAL ADDRESS.

(Concluded from page 151.)

These discoveries increase rather than remove our doubts as to what lies beyond, but their far-reaching results, of which the foregoing are but hints, are the product of the present decade of investigation, and we stand but at the threshold of these directions of biological research. They

serve, however, to show that "the results attained by those who have labored simply to extend our knowledge of the structure and properties of living things, in the faith that every increase of knowledge will ultimately bring its blessing to humanity, have, in fact, led with astonishing rapidity to conclusions affecting most profoundly both the bodily and mental welfare of the community."

The attitude of the community toward scientific study is primarily that of antagonism. Innovation provokes opposition. There are many years, but one sentiment, between the persecution of Galileo and the onslaught on vivisection; 1616 has somewhat of kinship with 1884. To the great mass, whose interests are mainly confined to the harsh treadmill of life,

"Storing yearly their little dues of wine and oil,"

scientists and scientific study are a matter of indifference, not infrequently mingled with contempt. Popular government has never initiated any movement to promote research, for that implies a cultivated sentiment among the voters, and the English-speaking nations have done almost nothing in the way of State appropriations for scientific study. Germany, France, Russia, Holland, Belgium, and Italy are, almost exclusively, the originators of the later methods. From their laboratories have come the great discoveries of modern times, and this because in these countries the laboratories have been under State patronage. The most that has been done in England and the United States has been done by those men whose capacity for scientific discovery has been accompanied by the possession of private fortune; the remainder has come from work incidental to the occupation of professorial chairs.

Professor Lankester, in an address to the biological section at the late meeting of the British Association, has gone over this subject in detail, and, while he has provided nothing new in the way of argument in his comparison between the scientific resources of England and Germany, he has stated some interesting statistical facts. While Germany, with its 45,000,000 of population, has 21 universities with 100 institutes devoted to the prosecution of biological study, providing posts for 300 investigators at an annual cost to the State of about \$3,000,000, the annual expenditure of the 21 universities being about \$4,000,000, England, with its 25,000,000 of population and its greater wealth, has but 4 universities, which possess endowments and professorates containing but 38 positions. The author quotes the prime minister, who has taken much interest in science and learning, as saying that the \$135,000, the capital sum expended on the Nottingham College of Science, "was a very important contribution to the support of learning in that country."

In this country, neither the nation nor, to my knowledge, any State has done the first thing to further scientific research directly. Much has been done for industrial education, and a great deal of research is really carried on under cover of State and Government appropriations, but all is of secondary moment to the powers that be. We have in the Government the Geological Survey, the Coast and Geodetic Survey, the National Observatory, Museum,

Nautical Almanac, Signal Service, etc., and in the States the Fish Commission, State Geological and Topographical Surveys, Museums, Laboratories, Agricultural Stations, and what not, but all were established (and receive their support in view of the work they do) for some "practical" end. Valuable results have been obtained by the great and admirably conducted exploring expeditions in the West, but these have been incidental. The surveys had a practical aim which would have been accomplished without the scientific observations and the collections which were made. Similarly, the valuable observations of the Signal Service form contributions to scientific theory and practice, but the end is practical. The same may be said of the National Observatory at Washington. The Smithsonian Institution indirectly combines research, publication, and collection. It has been magnificently managed from the first, but it was the endowment of an Englishman. The State Survey of New York and Pennsylvania, the former under Professor Hall, the latter under Professor Leslie, have been prosecuted with a similar utilitarian purpose, though the results as published are a noble contribution to science.

Scarcely any provision has been made until recently for biological science in an institution of learning beyond elementary instruction. New research is contemplated in a few, notably in the Johns Hopkins laboratory and in the investigations by Dr. Martin in Chesapeake Bay and at Hampton. This enterprise is due to private beneficence, and its results, especially in investigating the various modes of propagating the oyster, have induced the State to promote further studies in this single direction. Alexander Agassiz's laboratory at Newport is supported entirely by his private purse. Professor Baird's work, viz., that of the U. S. Fish Commission at Wood's Hole, has certain facilities placed at its disposal by the Government, as a revenue cutter for soundings, etc., etc., but this was originally and mainly the work of the Smithsonian Institution, and remains in great part the same. The Museum of Comparative Zoology at Cambridge is due to the enterprise of Louis Agassiz, though the State gave in its aid \$293,000 in various bequests, while private individuals have given about \$696,000.* President Eliot said, in an address in New York, that Alexander Agassiz's gifts alone were worth nearly \$1,000,000. He has built, at his own expense, a large addition to the museum.† George Peabody's gift practically adds to the resources of the museum, though given for a specified purpose and under separate control. In some branches the museum surpasses in its collections the British Museum and the Jardin des Plantes. Research is not the primary object here. Agassiz's idea was to teach students how to observe nature, to educate naturalists; but the great collections and the original investigations are now first, though courses of lectures and instructions are given. The Peabody Museum at Yale is due to George Peabody and to Marsh's private fortune, while Cornell University, in this State—which publishes bulletins of investigations by Professor Comstock in entomology, the diseases of fruit-trees, etc., by Professor Prentiss in botany, and others in agricul-

* Report of 1876.

† Report of 1880.

tural chemistry, veterinary diseases, etc., where Professor Law is conducting a valuable series of experiments regarding inoculation for pneumonia—is again private munificence, supplemented by the national land grant, which latter did not contemplate anything but instruction. This review includes most of the various scientific institutions which exist in this country and afford facilities for original research. There are, of course, several astronomical observatories which have been established by private beneficence—as the Lick Observatory in California, the Swift at Rochester, the Dudley at Cincinnati, and others; but these only illustrate the rule.

The facts do not prove the basis of complaint. The scholars must always be the select few. Their audiences are gathered from narrow limits, and, though their influence is to the bettering of the race, that influence is slow in diffusion. Scientific work is unselfish and not mercenary. Its productions possess but rarely any marketable value. Its inspiration is the discovery of the true, and the zeal displayed has in it no element of personal aggrandizement. "There is generally little or no pecuniary reward for the success of men of science. The public do not eagerly crave each new memoir on the higher mathematics. A crowd does not gather around the bulletin to read the discovery of a new asteroid or organic radical." The bacillus of malarial fever might hollow out the historic niche for its discoverer, though the discovery would not sell for a dime.

The pursuit of that selected and diverse learning which makes up the body of medical science is entered upon and becomes an absorbing passion from motives other than the expectation of livelihood or emolument. Once within the arcanum and groping among the shadows and mysteries and uncertain footholds of the strange land that lies above and below and around the crowded places, where the strife for existence and human greed trample one upon another, men will wade through misfortune, suffer privation, endure hardship, and smile at penury, tranquil in the assurance that, if indeed they do not themselves enter the promised land, they will have made part of the road smoother for those who are to follow them. It is easy to see the force of what earnest men have plead for, that the tone and breadth of the civilization would be strengthened and enlarged were the community to recognize the ministry of its workers in science and foster their efforts; but the attitude of the public does not favor the expectation that this can be. The cultus of medical science must continue to share the experience of all original investigation, and remain a personal factor among the diverse directions of human industry. Multitudes stand ready to seize the results of its labors and apply them, in ways that men can understand, to the satisfaction of human need. They who cull the flowers, enjoy the fruit, reap the harvest, or sell the crop, are of different mind and other station than they who till the ground, plant the seed, nurture the sapling, and wait, through recurring seasons of sun and snow, till the sturdy limbs are shelter and refreshment to the unthinking life that recks not of its benefactors. There is a medical science; but if medicine were a science only, there would be fewer medical schools than now exist.

There is an art of medicine, and its multitudinous votaries attest the fruitfulness of its pursuit.

In 1880 the States and Territories of this country held a population of 50,155,783, and of these 85,671 persons were enumerated as either physicians or surgeons—a proportion of 1 to 585. In the State of New York there were 5,082,783 persons, of whom 9,272 were doctors—a proportion of 1 to 548. What the ample front doors of the medical colleges, with the signatures of numerous licensing bodies, have done during the past four years to swell the total, it would be hazardous to speculate upon. But these salutary, health-forecasting, and longevity-producing statistics stamp the effete and tottering governments of Europe with the die of derision in their infamous disregard of human comfort, and put an extra gilding on Columbia's protecting ægis, prolonging the beauty of her daughters and the bravery of her sons; for while the proportion of doctors to population in Switzerland is 7.06 per 10,000; in Italy, 6.10; in Hungary, 6.10; in England, 6; in Austria, 3.41; in Germany, 3.21; and in France, 2.91, the United States, with their 17.1 per 10,000, have consummated what Berkeley foresaw but did not dare to write—*Westward the doctor's empire has full sway.*

The causes of this disproportion are complex and do not rest on the surface. If primeval man had no doctors, if the barbaric cultivate here and there a medical fetic, if the semi-civilized and the savage at times listen to the incantations of a medicine man, if free air and simple habits do not crave the overflow of medical schools and the smoking chimneys of manufacturing chemists, then this great polyglot population, "in the foremost ranks of time," with its superfluency of civilization and the interwoven tinsel and solidity of its citadel, must have need of this great standing army "to guard the chinks of stone against calamity."

When it is considered, what every one knows and what would be very difficult to put in statistical array, that large and sparsely settled sections of the country are below the average supply of the ratio of population to doctors, that a very large proportion of the population is not so materially favored as to contribute the average quota to the support of this body of men, it would appear at the first blush that the jeremiads, that have been pronounced by the pessimists over the decadence of the race and over the increasing disabilities of the people, superinduced by the demands of this intense civilization, had not been overdrawn. For though it is fundamental in political economy that demand creates supply, it is also true that supply creates new demands, yet beyond the point when supply exceeds demand the supply begins to shrink. In the considered case the demand seems not to be satisfied, for the number of doctors is increasing year by year, and that out of proportion to the increase of population, for the ratio is likewise becoming larger. Some solution of this problem may appear further on.

Taking this State, for instance, and averaging the income of these men at the very modest sum of \$1,000 per annum, the sum total of their annual receipts is equal to the entire receipts of all the charitable institutions in the State for the last fiscal year; and equal, also, to the amount expended on the public schools in the State during the same

period—a total of about \$10,000,000. As this average represents a cash income of about \$3 a day per man, the basis of calculation is ridiculously small. Applying the same average to the entire force of medical men in the country, the total income of the profession would be some \$12,000,000 in excess of the total product of the precious metals during the past year. These are conspicuous comparisons, but one can form his own judgment as to how far these estimates are below the actual facts. However estimated, they serve to show a liberal provision for one class of men, who, with due explanation, can not be said to belong primarily to the producing interests of the country. As a means of livelihood, the profession of medicine is attractive, and little wonder need be that its ranks do not on this account suffer depletion.

From the social standard the profession elevates the man, no matter of what stuff he is made, if he does not ostentatiously disgrace himself. If he goes into Coventry, he goes in spite of the strong sentiment in favor of his guild, which would keep him back if it could. There are social grades, and physicians to fit each, and in each he is easily at the top, for no other class of men so promptly secures social place and recognition. The fact is patent, and this impulse is certainly not insignificant in the choice of a future.

Combining the certainty of livelihood and the assurance of position, it will in this day hardly be questioned that no other walk in life, in professions or affairs, holds out such positive promises of immediate reward and of continued permanence, to men of all ages and grades of ability, as does the medical profession. Coupled with the growing distaste for downright hard work and the scramble for the easy places, facts go to prove that, with a determination not to outrage public opinion and an avoidance of nomadic tendency, any man, no matter what his antecedents of deficiency of culture or failure in vocation, endowed with his doctorate, has an unshakable foothold in life. Despite the fact that every member of the profession is perpetually the recipient of sympathy from his clientele over his engrossment of time and irregularity of sleep, there is a larger success per thousand, with less bankruptcy, with freer and more varied opportunity, than belongs to any other class in any of the lines of occupation along which men grope their way through time.

It is superfluous in this presence to relate how gentle the acclivity that appears, how wide open the portals that invite, how roseate and verdant the paths that gladden, how radiant the sentinels that summon and assist the novitiates on their way to these easily acquired places of esteem and support. With one chartered medical school to each half million of population, and the licensing authority of a vast number of other corporations, the invitations to the profession are as urgent as the gifts of the degree are lavish. The restrictive barriers are so loosely set up, and the final test of fitness so daintily applied, that the former are cast down as easily as the latter is overcome. That a strong professional pressure and a sense of the fitness of things have elected some institutions to take a vigorous and exceptional stand on the side of rigidity, making their diplomas an assurance of capacity and a promise of an industrious and

honorable career, does not affect the influence of the fact that in law, privileges and immunities, all diplomas are on a level. There is not even the seclusion of an open secret. There is the common knowledge among medical men that their ranks are recruited continually with men who but yesterday stood behind the counters and desks of all kinds of business, and who, by accident or vagary, suddenly were translated behind an office sign, having accomplished the distance in accord with the most perfunctory of formalities in the minimum of time. Whether this is wise or unwise, right or wrong, is not in the drift of this paragraph. The facility of admission is the pertinent fact.

The time was, and the fiction has not wholly faded from common speech, when law, medicine, and theology * were denominated the *learned professions*, as distinguished from the professions of the army and navy, because a university education was a prerequisite to these special studies. To-day, in the multiplication and distribution of special knowledge, this discrimination does not hold. The influences for the promotion of knowledge, and the manifold appliances of educational machinery, have lifted up the entire people to a higher plane of culture than any previous generation has enjoyed; and the classes of journalism, literature, and the polytechnic forms of industry, wherein certain lines are cultivated for purposes of livelihood, contain, within each, an amount of general learning which can creditably accept the wager of any competitive comparison. Without abating one jot of regard for the supreme advantage of early liberal education, it is nevertheless true that there are, in numerous professions and occupations, multitudes of instances of a liberal education not constructed within college walls. The profession of medicine has not kept her distinguishing place. Not that great men have arisen in other and various walks of life; that is in the spirit of the time. Not that she has not had exponents in every decade who have been the peers of the best; that is within the facts of her history. Not that general knowledge has increased so that her individuality has been lost; that would tacitly deny her immense scientific advance and obscure the progress of her art. But her recruiting sources have been so many, her safeguards of loyalty have been so weakened, her probationary tests have become so insignificant, that, however smile-provoking may be the mention of the wig and cane, there is scarce anything left of the old spirit of the knight and the *preux chevalier*; and the proportion of medical men who are in accord with the medical profession at its best, both in knowledge of its results and in capacity to do, is rapidly lessening with the years.

There is an inconsistency in all this which does not mitigate the complexity of the problem. The profession has never lost sight of the sacredness and importance of its trust, at least if spoken words are not hollow and meaningless. Glowing periods of earnest speech have, over and over again, proclaimed its ministry of helpfulness, the value of human life to family and affairs, the supreme necessity of single-mindedness in this work of mercy, the rewards that come, estimated in approving conscience if not in coin,

* In 1880 there were 64,698 clergymen and 64,137 lawyers in the United States.

the need of persistent study and a ripening culture, so that, faithful to his profession and loyal to his guild, the physician may be inspired to unite the utmost wisdom of his time with the gentleness of sympathetic manhood in restoring the stricken to the activities of life or soothing the inevitable passage into the beyond. These are familiar themes. And also the inconsistency appears in the fact that there are no grades of responsibility. Men talk of important cases; they mean, not gravity of disease, but the surrounding accidents of family, wealth, friendship, and important trusts which stand in jeopardy of disruption or shock. And yet who shall stand arbiter over the relative value of human life? While it can not be expected that all physicians shall be those who, endowed with varied resources, "unite the natural love of healing with the highest spiritual development," yet it would appear as if those who are to stand on equal terms with the best, share the like responsibilities and stand face to face with similar duties, should give some adequate guarantee of fitness.

If these statements misrepresent the facts, no charity should be permitted to condone the mistaken zeal that would abuse the opportunity of this platform and cast slander and reproach on the profession; but if the statements are true, the safer plan is to examine the facts, and it is privileged to follow up the consequences.

The profession of medicine, at its best and in its ideal condition, includes a body of men who, instructed in the medical sciences, studious in the observation of bodily disorder, conversant with the normal type of bodily condition, acquainted with the causes that subvert the normal type, expert in recognizing the tendencies to dissolution, and skilled in the devices that alleviate and restore, offer to serve the community for a consideration. The end of all medical learning is to make sick people well, to assuage the discomforts of the incurable, and to promote the euthanasia. Abstracting this, medical science, with the splendid results of its erudition and the achievements of its recondite research, is but a department of zoölogy, the natural history of the animal—man. The profession does not occupy a professorial or oracular tripod, from which knowledge is dispensed on an endowment or a salary. On the contrary, personal time and labor are furnished, on which a price is set. There are no boundaries within which any one member has the monopoly. The restraints to destructive competition are based on the recognition that the wisdom of each is dependent on the experience of all.

The matter of compensation for medical services has been handled with many degrees of sensitiveness, but, no matter what the particular fashion—of voluntary honorarium or established fee—the fact remains that the arts of medicine are practiced as a means of livelihood. It is contrary to the popular understanding, but still the fact, that the cases where money is amassed from the practice of medicine are very exceptional. This compensation is governed by a variety of circumstances; but the rule holds generally true, that in any given locality or special department the best is the most fully favored. "We still talk of ancient heroes, and even the luster which clothed winners in the Olympic games, but nothing which the strength-worship-

ing Greeks could bestow in the way of popularity or public honors was comparable to the fame and substantial profits which fall now upon a man who much excels his fellows in no matter what."

Of course, it is impossible to estimate how many of these 80,000 doctors confess the faith and reverence the lineage that are confessed and revered in this body, but it would be idle arrogance to assert that universal dishonesty is characteristic of the remainder which the community is content to employ and compensate. When it is clear that the trade instinct does not exist in our own ranks, it will be time to attack competition on this ground. That special medical arts should be selected for purposes of trade, is derogatory to the best interests of the profession as a whole; but where medical men are so numerous, and livelihood is at stake, competition will choose its own field of operations. It will hardly be doubted that the desire to benefit the patron is strong in most that practice medical art, and that no class of practitioners is callous to failure.

The sense of loyalty to the heritage and mission of medical learning has been so instinctive in its history that any suggestion of its trade instincts has been met by prompt rebuke; and men have stood ready and valiant to oppose the charge that mercenary motives were the inspiration to the daily deeds of mercy and kindness, of forbearance and sacrifice, which have been its crown of glory, and which none but those who have borne the burden and endured the trial can ever know. It is, however, not only likely, but true, that the increase of workers in a field whose natural product would be sustenance for a less number would develop ingenuity whose artificial forcing would prove a detriment to the soil. If impositions are practiced, if needs are multiplied, if deceptions are instilled, so that the confidence of the community is abused or made subservient to the material growth of any part of the profession, to that extent or in that direction the attitude of the profession is hostile to the best interests of the community, and the hostility is provoked by the mad rush into its ranks, which neither the profession nor the community have taken any measures to control. There is no need of the apology of this hypothetical statement. Charlatany is rampant, and the name of doctor covers lies and practices which are a ruin and a curse to the people. Those who are true are for ever on their defense against their titular parasites, and the stand for honorable manhood is weakened by the assaults of its irresponsible foes.

In the multiplication and precision of the medical arts, in differential diagnosis and the consequent enlarged nomenclature, in the multifarious forms of therapeutic appliance, and in the bold interferences of surgical practice, the best of the profession stand equipped with information and resource far in advance of any period of its history. By reason of this, its responsibilities are increased, and the demand is greater for the exercise of conscientious and intelligent critical apprehension of the particular conditions to which this analytical knowledge is applicable. A good physician is not necessarily a learned man. Experience, sagacious observation, strong intuitive perceptions, with the minimum facility in advanced appliance, have made, and will continue

to make, successful practitioners of medicine. But these are not the teachings of text-books, and are not the themes of the medical lecturer. However, it will hardly be questioned that skill in differential diagnosis is the safe basis of treatment, and varied resources in medical art lead most rapidly to the best results; and the faithful student in the profession is the one most keenly alive to the importance of both. When the pre-eminent importance of accurate diagnosis is considered, when the difficulties that environ its acquisition are appreciated, when it is understood how patient and enduring are the observations that lead up to the mastery of the nomenclature of medicine and the comprehension of the varied conditions it represents, it is humiliating to hear the most profound disorders that afflict mankind bandied about in common speech as the veriest playthings of the hour. The diphtherias that come into homes as plentifully as summer showers over the landscape and pass away as soon; the peritonitis that disturbs the quiet of the night and is dissipated with the morning dew; the pneumonia and spinal meningitis, that early recognition and prompt specific lead in a few days to vigorous health, are all recounted, with flippant unconcern, in drawing-room and social circle, on the highway, in the mart. These are not the manufacture of the people, for the terms are foreign to domestic culture. It were refined cruelty to charge upon the doctor such consummate ignorance; better far to credit him with the knavery that can command untruth to advance his interests of fortune.

On the other hand, it is asking too much of credulity to believe that the attitude of the profession is friendly to the community when the lavish gift of the doctorate puts into so many undisciplined hands the medical arts which are as potent for evil as for good. Is it too much to assert that uncertainty of diagnosis runs parallel with the free use of drugs, and that confidence in specific therapeutics decreases with experience at the bedside? What inferences are deducible in this direction from the multiplying drug-stores and the rapidly enlarging business enterprise of the great manufacturing chemists? Is it supposable that the ingenious activity of pharmaceutical industry, in devising the protean forms and potencies of foods and medicine, is all on the side of the public interest? Does it appeal to the public direct, or is it profitable through the medium of the profession, who act as agents to benefit the manufacturer at the expense of the people—the only commission being the desertion of the tried for floundering experiment with the novel? Does the per centage from the truss-man and the druggist mean anything more than the struggle of incompetency to eke out a livelihood at increased cost to the people? Is the community safer with broadcast hypodermic morphia, aconitia, and strychnia (vegetable medicines forsooth) than with a blind surgeon exsecting a tumor from the axilla? Whence comes this malaria, that has jaundiced the speech of men, but from the track of the scapegoat making for the wilderness, burdened with the easy diagnosis of lazy incompetence? Has the clinical thermometer proved an unmixed good, when every pyrexia is the impetus to indiscriminate quinine? and who is responsible for the "one-cent-a-grain in pill or powder" that blazon in the sunlight, through

colored globes in shop-windows, along every thoroughfare? Has the speculum contributed to the moral sense of the community, while prurient or needless interference, with most cruel vandalism, is invading the sanctity of the home and making the daughters of the land wise before the time?

Humiliating and unsavory though it be, the regnant fact holds true that—coupled with that large body of men who acknowledge an ancestry of scholars and faithful students of nature, who base their art on principles which have survived criticism, who practice their art in the interest of the physical and spiritual well-being of their fellow-men, whose livelihood is a legitimate product of their worthy and acceptable service—there is another and large class, known not only to the census enumerator but to the community by the same name, with equal protection under the law, who, with insufficient culture and consciences dulled through habitual and ignorant tampering with grave responsibilities (described lately, by an influential medical journal, as "hangers-on of whom any party would be ashamed"), are a standing menace to the community, which, accepting all as competitors in the race, gives to all alike its patronage and its support.

While the history of research has proven that the community has been slow to recognize its duty to scholars in facilitating their inquiries into the facts and phenomena of physical life, which have developed laws and expedients so important and far-reaching in their influence on the well-being of the race, yet the contrary holds true in the attitude the community sustains to medical art. Certainly, in this country at least, in the broadest sense, up to the limits of its education, the community has been a lavish patron of the agencies that alleviate disorder, and a co-worker in enforcing the instrumentalities that prevent disorder.

It seems a little absurd and contradictory that a life-insurance company, whose assets are counted among the many millions, amassed through operations based on laws of heredity, statistical tables of mortality, the understanding of normal life, and the natural history of diseased conditions, all of which are the product of the industry and acumen of medical men, should consider three dollars an equivalent for decision on a proposed risk which would mar or make its thousands. But it must be considered that special knowledge has a marketable value, according as it is possessed by the many or confined to the few. It is the characteristic and the glory of scholars that their labors are a free gift to mankind, while the acquisition of knowledge, and the skill to apply it, are in the free opportunity of any and all who may choose to avail themselves thereof.

Whatever may be the criticisms leveled against the conduct of dispensary and hospital services, and apart from all considerations that attract appointments thereto, it seems somewhat contradictory that the benevolent instincts of Christian civilization that cares for its poor, its helpless and infirm, should accept as a gratuity, not the knowledge of the means of relief which is free to all, but the personal time and service of those who have acquired the means of applying the knowledge that relieves society of its burdens and restores its pensioners to the ranks of industry and self-support. But here also it must be remembered that the

capacity to relieve is the instinct to ungrudging service, and, through all the history of medical art, in public institutions and wherever in private life distress has been found, the best gifts of the best men have been freely offered, without the least listening for the clink of coin.

If the serpent had never trailed his way along the Euphrates's banks, primeval man might have been in this audience room, and biological science might have spent its energies in extracting the secrets of normal life; but "by sin came death," and medical science exists to delay the inevitable doom. The community shrinks from the approach of dissolution and simply asks of medical art that its pain be relieved and that it be restored to the plane where its activities may have full play. The saint calmly and intelligently looks death in the face; but the community is not a saint, is not calm, is not under the control of its intelligence, and, while there is hope of life, its emotions have the mastery, and it accepts any promises with docility and in full faith. The stolid indifference to life in the barbaric races is replaced in the higher civilizations by an intense clinging to life, and the fear of death is the universal passion. Intelligence is in abeyance in alarm. If rational medicine marvels that its claims have not met with universal acceptance, it must admit that it has embraced too many incompetent interpreters and that its claims have not been properly presented; or it must also accept the common lot of advancing knowledge, which is always ahead of the community, labor assiduously and wait patiently, amid opposition, for that larger culture which is of slow growth, when reason dominates emotion, and where superstitious awe, in the presence of the unknown, fades before enlightened comprehension of scientific truth.

Certainly the community is not slow to accept the offers of mercy, for, while it submits patiently to all that is ordered by the profession, takes all its medicaments, undergoes all its operations, awaits the results of all its experiments, and unhesitatingly believes everything it says, and quotes it, more or less correctly, for the neighborly benefit, the community, in its charity toward all, does not allow the profession monopoly in the practice of medicine, but, with its faith in drugs and measuring their efficacy by the violence of their operation, it swallows, on bare printed promises, \$60,000,000 in proprietary medicines per year, and assists the fortunes of drug dealers to the extent per annum of \$80,000,000 more.*

Such bold and childlike confidence is rudely shocked when a cosmopolitan daily asserts that "expert testimony no longer occupies the place in public esteem it once held";† when a well-known lawyer‡ charges in open court that "you could buy the most honorable members of the medical profession as you could horses in the open market"; and when a judge passes by the claims of the alien-

ists* and appoints a dermatologist and a gynecologist (both excellent men) as a commission to examine a man on a lunacy writ. But these assaults on virtue are not without parallel, and the fact still holds that the attitude of the community to the profession is eminently docile and receptive.

On the other hand, the profession has no just complaint against the attitude of the community in the exercise of its law-making functions. I am not aware that any Legislature has ever initiated any statute designed to restrain the freedom of the profession. On the contrary, the law-makers, in chartering medical institutions and societies and in legislating for the apparent protection of the people, have granted about everything that everybody with a claim to respectability has asked, distributing immunities with a free hand. That legislation has not infrequently been contradictory in any one State and multifarious in the country, by reason of the numerous law-making bodies, enforces rather than impugns the considerate attitude of the legislators in their respectful reception of professional petition. The direction of professional effort is so clearly in the public interest, and so removed, in every detail, from clashing with the public interest, that those who look to the Legislature for relief and protection have reason to be assured of an unprejudiced hearing.

The convictions of medical men in the direction of sanitary precautions are so strong, and the theoretical argument in favor of these precautions is so convincing, that criticisms, amounting at times to denunciation, have been freely expressed in the medical press and in conventions for the discussion of these subjects; on the one hand, against the apathy of the individual in not acting upon sanitary information so freely given, and, on the other, against the hesitancy of the law-makers, State and municipal, to legislate radically on these matters. It will not hinder the work of sanitary reform if it is kept in mind that the argument is not yet concluded; that the utility of "costly and troublesome hygienic devices" has been called in question; that medical men themselves have not mastered the subject, and are very far from being agreed as to details; that there is no inconsiderable share of the people who look upon sanitary interference as an invasion of their personal rights, and that public health laws can so easily be made an engine of oppression. If it could be proven that the filth diseases never occurred in a house where the known conditions of perfect sewerage were fulfilled, there are plenty of citizens who would exhaust the last intricacies of the plumber's art to fulfill those conditions for their own personal safety; and if it could be proven that these same diseases could not occur in a city or a State under similar conditions, there would be a moral obligation on the law-making bodies to levy appropriations needful to fulfill these conditions. But there are many factors wanting and unproven in this and other sanitary problems, and, in default of accurate and exhaustive knowledge, legislators must move warily before setting in motion the machinery of a statute. The journals are not wanting in the cards of "consulting sanitary engineers," whose warrant for the title is more or less obscure, and the sign-boards of the "sanitary plumber" meet the eye at

* These figures are doubtless far below the actual facts. The census reports 563 patent medicine establishments, producing \$14,682,494, and 8,592 drug and chemical establishments, producing \$38,173,658. Three times this amount, distributed through the 30,000 drug-stores, would give an average total sales for each of \$5,000.

* Judge Cullen in the Van Augen case.

every turn; but men may be pardoned who decline to accept implicitly the opinion of the one or the handicraft of the other. Information of this kind is not confined to a class, and men naturally chafe under oppression. When it is considered that within fourteen years twenty-nine States have authorized State boards of health, with large facilities for investigation, there is much to hope for and little to discourage in the friendly attitude of the community. On the contrary, the profession will look, with great inquisitiveness, for the conclusions at which these State boards may arrive.

And once again the instances are apparently increasing where the appointing power has seen fit to nominate other than doctors of medicine to the administrative offices in local health boards—an exercise of executive function which has been duly reported to the medical journals as a grievance. If such a health officer is to exercise discretionary powers, or powers plenipotentiary, then the appointment of other than a medical man is a grievance, for none but he is supposed to possess the information qualifying for the exercise of such powers. But if the functions of such an officer are purely administrative, to execute certain well-defined provisions of a statute, such an appointment is not a grievance. On the other hand, it may safely be called in question whether the habits and culture of a medical man are such as qualify him to best discharge such duties. And it is a matter of much more serious moment whether the delicate questions that must necessarily arise in the execution of a health law in a large community can rightfully be left to the decision of any one man.

But there is another view of this matter. The various information which is included in what is being called sanitary science is not the resultant of any one man's observation, nor of the men of one period, but a gathering together of the experience of men from remotest history. The scholarly element which enters into the slow accretions of all science prevails in this special department. It is intrinsically an integral part of medical science, and, like all scientific truth, it is a gift to universal knowledge. Once given, it can not be withdrawn; and, once given, it takes its place among the sources whence the community draws its inspiration to a higher civilization. It differs to-day from any past period in that more exact and larger methods are employed in its study; and, in common with all other special knowledge, its area is widening and its affiliations with kindred knowledge are multiplying. Like all other knowledge, it will have its epochs, and these epochs will be coincident with certain applications to human welfare; but, with each epoch, new applications will be defined wherewith the wiser sense shall raise to a higher plane the dependent brethren who need protection and support. Beyond the period when the people have appropriated the principles and formulated them into rules, and always in advance of the common thought, will be found the scholar still searching for the undiscovered, and still adding to the knowledge out of which are to come the wiser rules for the production of better men. The outlook of a healthy and guarded community is more beneficent by far than the possible chances of a community threatened with the shadow of calamity.

To claim that the medical profession is entitled to the emoluments of office in the execution of sanitary laws, is to claim a royalty from the engineer and the plumber; and, because its ancestry discovered that soil-saturations from privy-vaults in crowded localities is inimical to the public health, its descendants should have precedence in the competition for the office of night-scavenger. Devices, not principles, are patented. Medical men *must* always be advisory, executive they *may* be; but to hold their executive seclusion as a grievance, is to abuse the genius of their scholarly guild. The establishment of the various boards of health—municipal, State, and national—is the one great acknowledgment the community has made to the achievements and helpfulness of medical science; and this recognition is a gratifying recompense to all who have contributed to the result, and an unfolding promise of reward to all who may labor in this direction for the bettering of their kind.

If sanitary science really contains the "promise of the potency" its advocates claim, and if its results should become formulated into laws for the sure protection of large communities, the reciprocal attitude of the medical profession and the community must in the mean time have undergone many radical changes; so radical, indeed, that the imagination might snap in the stretch to compass them; so radical, indeed, that the "goneness" of "Othello's occupation" would be nowhere in the immense hollowness of that vacancy that once was alive with the busy ministry to ills, that then shall be but a dismal retrospect.

Of course, one can not fail to grant that each new medical school is stepping friskily into line with its predecessors to supply the "felt want" not only of the community but of the profession, and one may, in all charity, concede the utility of appeasing the unquenchable desire to teach; but one may also be justified in parting company with the practice of the period, and demand, in the interest of medical science, for the purity of medical art, for the maintenance of professional honor, and for the protection of the community, that the teaching and degree-granting authorities be *not* one and the same. Let the community, through its law-makers, legislate into control an acceptable judicial body, in which shall rest the decision of the fitness of candidates to assume the responsibilities, enjoy the honors, and reap the emoluments of professional life, and the sharp contests of dogmatic rivalry, the destructive wiles of medical harpies, and the weakening competition of medical schools would be rapidly equalized in the "survival of the fittest." Fitness is, in some sense, a test of honesty, and this safeguard the community has a right to demand.

No man has an inalienable right to practice medicine. He can choose to do so, but the public may adjust the tests of his fitness. When the great interests of the community are to be subserved, and when the community is incompetent to judge of the accuracy of details and the correctness of results, and, by the nature of things, never can acquire the competency to judge, the community is bound to seek its protection in exacting compliance with tests formulated by experts. "The doctrines of free trade can not be applied to professions. There can not well be true freedom of trade where the power of judging of the article traded

in or demanded is all and only on one side. It is for this obvious reason that the spirit of free trade has not been and can not be applied to those avocations commonly termed professions. The inhabitants of civilized countries, having desired legal or medical assistance, and well knowing that they were unable to form any immediate judgment on the quality of that assistance, have looked for and obtained external means of protecting themselves from bad law and bad medicine—means external to themselves. Such communities have required that lawyers, doctors, and others should give some evidence of qualification to official examiners, or have aided professional men to erect certain social barriers, known as etiquette and the power of the cold shoulder, for the exclusion of quacks, charlatans, and other unqualified persons from their ranks."*

"A grave question arises at this point, whether society has not a right to protect itself against the spread of these delusions; whether, indeed, it is not the duty of the Commonwealth to interfere. For it is the very essence of charlatanism to misdirect the feeble, while the natural consequence of indulgence in error is to still further vitiate and impair the mind. The quack who makes a living out of the follies of mankind is apt to be contemptuously dismissed by the sane as a minor evil-doer, as a scourge who may whip fools into wisdom, but in this view of the case, namely, that he is increasing the public burdens by undermining the reason of his dupes; even while he fills his pockets by mocking the hallowed traditions of the people, he becomes a public enemy. Against him all good citizens, regardless of creed or school, are bound to unite for the defense of their helpless fellow-creatures no less than for their own protection."†

This is solely a matter of agreement within the profession. If it sees fit to ask the community to take back the prerogatives it has bestowed and readjust them, experience has shown that the attitude of the community to the profession is so friendly that the change of base of the degree-conferring functions could be readily effected on the easy demonstration of the added dignity of the profession and the increased protection to the community.

It is estimated that three fourths of those enumerated as physicians and surgeons are, up to the limits of their individual competency, applying to the healing of human ills the best methods of experience, based on the knowledge derived from scientific research. The remaining 20,000 are an *olla podrida* of every conceivable specialty, having the common bond of applying each his own special method of cure to all diseases. The particular mode of cure is the trade-mark to attract patronage. If any is honest enough to vary his method of cure, with the hope of benefit to his patron, he is dishonest to his advertisement. If any are so bigoted as to believe that one mode of cure is applicable to all diseases, or if any are so rigidly adherent to their special trade-mark as to apply it to all, regardless of all consequences save their personal gain, the community is not only defrauded but damaged. It would be idle to deny that each

trade-mark covers some truth, or that some useful thing has been the stock in trade of some peripatetic healer, as witness the carbolic-acid injection for hemorrhoids. It is very doubtful if scientific medicine is wanting in any of the appliances which, taken alone, are the stock in trade of the exclusive practices. One afflicted with an incurable cancer, having exhausted all open knowledge, meeting with discouragement and denied all hope, is pretty sure to flee to some advertised succor, to be again disappointed, and for the reason that these arts had been previously exhausted. This is all there is of the great body of exclusive practices, stripped to the skin. Granting honesty of purpose to all this motley crowd, the community may be benefited by the application of certain arts, but the community is deprived of the benefit of all the other related and substitutive arts.

The personal factor enters so largely into individual success in the practice of medicine, that the community judges of results mainly by its observations of the mode by which the results are obtained. The community is influenced less by a system of practice than by its confidence in the man in whom it has trusted. The community is as incompetent to decide upon the merits of the former as it is capable of being deceived by the skillful manipulation of the latter. This personal factor makes personal character take front rank in qualification for medical practice. The community may suffer seriously by its patronage of nostrums and exclusiveness, but the community undergoes greater peril, and the *esprit de corps* of the medical profession is outraged infinitely more by the incompetency to which it has given its diploma, and by the dishonesty and trickery in its ranks, which it sees and can not control. Whoever can deny the one or the other is blind to human frailty, and he is to be credited with angelic confidence too pure and ethereal for this "vale of tears." The physicians who are floundering through the uncertainties that ignorance imposes, or who abuse the confidence of the community for purposes of gain; who will take any other course than to tell the truth and employ the most experienced devices to secure the speediest results, are beyond the reach of all codes, whether of human or archangelic contrivance. And yet the profession, in all consistency having granted these the degree with a free heart and a Godspeed, must consult with them on equal terms, and, in an emergency, defend them in the public confidence. To turn a child from the door as an outcast is inhuman.

Read McMaster's delightful description of the Doctor in 1784; see the same men as they are adapted to the social relations in varying communities all through the land to-day, furnished with arts and information that make them acceptable by every hearth-stone; prepare, to fill their places, men whose accomplishments shall be the test of fitness; and, with the assurance that character is the result of responsibilities well met, and that character alone is influential to make the educating impress on the community, the day need not be far distant when the medical profession shall be in the wiser confidence of the community.

There is a laudable pride in occupations, and its basis is the consciousness of doing a useful thing well. To defend his heritage is the chivalrous duty of the scholar.

Lectures and Addresses.

THE CARTWRIGHT LECTURES

ON

METHODS OF STUDYING THE BRAIN,

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 6, 1884,

By BURT G. WILDER, M. D.,

PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

LECTURE I.

(Concluded from page 148.)

The examination of the simpler animal brains, or embryonic brains above mentioned (Figs. 11-13), should itself be prefaced by the study of schematic diagrams representing the brain in various stages of complexity, and these in turn may be made more intelligible by prior reference to analogous modifications of familiar objects.

FIG. 11.—LEFT SIDE OF THE HEAD AND EXPOSED BRAIN OF A FETAL KITTEN measuring 88 mm. from the top of the head to the vent. Drawn by Professor Cleaves. In this, and in Fig. 12, the five encephalic segments are visible, although the dien is represented only by the conarium.

In accordance with this suggestion, the encephalic cavities may be likened to the apartments of a house.

The primary components of each room are the *walls* and the *space* inclosed thereby. The walls are specially designated as *floor*, *sides*, and *roof*, and there are communications between each room and those adjoining.

A room may be extended in one or more directions, symmetrically or asymmetrically.

The walls may be thickened uniformly or locally. In the former case, the room itself might be reduced to a mere passage; in the latter, the original space might be transformed into an irregular labyrinth.

One apartment may be built up much higher than the next and overshadow it. The larger may even overlap the smaller, and its thicker floor become so attached to the roof on which it rests that removal of the former tears off the latter.

Let us now imagine that a house consisting of such a

series of apartments is completely enveloped by a continuous layer of tarred paper, and that its rooms are lined throughout with wall-paper, the ceilings and floors being covered with the same.

Now, it is conceivable that (1) the proper wooden wall of any apartment might be so reduced in thickness at any point as to hardly merit the name; (2) it might be omitted altogether along a given line, leaving only the two layers of paper; (3) a fold of the ental or lining paper might hang within the apartment; (4) between the two layers of the fold might be interposed a fold of the ectal or covering paper; (5) instead of a complete fold of the ectal paper there might be supported in the fold of the ental some looped strings or fringes connected primarily with the ectal layer.

It is also evident that (1) while the fold of ental paper is really projected into the apartment; (2) the fold of ectal paper, or the strings or fringes of that paper, are covered by the ental, and are therefore not *really* within the apartment; (3) any force applied from within or without will be likely to tear the wall along the line of interruption of the proper wooden wall, corresponding with the line of reflection of the ental paper therefrom to form the fold.

FIG. 12.—DORSAL ASPECT OF THE BRAIN OF THE FETAL KITTEN SHOWN IN FIG. 11. Drawn by Professor Cleaves. The names of the special parts are at the right, and at the left the names of the encephalic segments represented thereby. Excepting that the thalami are concealed by the hemispheres, the brain is readily comparable with that of the *Necturus* or of the frog.

After these easily apprehended statements of the possible transformations of a familiar structure, there need be no difficulty in applying the same ideas to the modifications of the brain.

FIG. 13.—DORSAL ASPECT OF THE BRAIN OF A HUMAN FETUS; $\times 15$. Drawn by Professor Cleaves. Notwithstanding the great size of the cerebrum, all the encephalic segments excepting the dien can be seen. The right hemisphere presents depressions, some of which are probably the precursors of true fissures, but this question can not be discussed here. The roof of the metacele was torn off in the preparation of the specimen.

Now, however, comes up the question of nomenclature.

To the beginner, the unfamiliar names of the numerous encephalic parts, even when reduced in number and length, as will be proposed in the closing lecture, form a real and

serious obstacle. With students, therefore, few special names should be introduced at the outset, and the general ones should suggest familiar objects and conditions; such, for example, are *floor, roof, sides, lining, sheath, pipe, brace*, etc. But on the present occasion there is no objection to the immediate use of the technical terms which will be employed throughout.

Since several of these terms are based upon the names adopted for the several encephalic segments, it may be well to say a word respecting them. As already stated, the recognition of the segmental constitution of the brain commits no one to the acceptance of any particular number of segments, but with regard to one segment there seems to be little or no difference of opinion. From the "middle cerebral vesicle" of the embryo is developed the region which is so prominent in the early stages of development (Fig. 1), whose floor forms at least part of the *Crura cerebri*, whose roof presents the elevations known as *Lobi optici, Corpora bigemina, Corpora quadrigemina, nates et testes*, etc., and whose cavity is anthropotomically designated as *Aqueductus*

Sylvii, or iter a tertio ad quartum ventriculum. Von Baer, called it "Mittelhirn," which becomes "midbrain" in the English vernacular, and technically *mesencephalon*, which I have shortened to *mesen*.

The determination of the number of additional segments involves many considerations, and any view of the question must be tentative for the present. For example, there are grounds for the opinion that all the parts caudad of the mesen constitute a single segment, of which the cerebellum is merely a "local hypertrophy." Since, however, some definiteness is indispensable to an intelligible discussion of the subject, I have adopted provisionally the view indicated in the accompanying figure of the segments of the cat's brain (Fig. 14) and in the diagrams (Fig. 17). It has the practical merit of recognizing a segment for each of the five principal masses or apparent pairs of masses which, named in order from the myelon, are commonly known as *medulla, cerebellum, Lobi optici, thalami*, and *hemisphære cerebrales* or *cerebrum*; Fig. 14.

Fig. 14 illustrates the following points:

FIG. 14.—MESAL ASPECT OF THE RIGHT HALF OF A CAT'S BRAIN DIVIDED SO AS TO SEPARATE THE FIVE ENCEPHALIC SEGMENTS: $\times 1.5$. Drawn by Mrs. Gage. These are parts of the same brain, but the difficulty of making the intersegmental transections without injury is such that, for ordinary purposes of a diagram, it would be easier to prepare each segment from contiguous segments from different brains. Part of the chiasma had to be left with the proen, and part of the precommissure with the dien.

The heavy black line represents the *endyma*, the lining of the *cœlie*, and its divided ends are connected by dotted lines.

The following abbreviations occur: *apx.*, *aulplexus*; *cn.*, *conarium*; *Cs. h.*, *Commissura habenarum*; *dc.*, *diacelia*; *Fm. Mg.*, *Foramen Magendie*; *hph.*, *hypophysis*; *mcs.*, *medicommisura*; *mec.*, *mesocelia*; *pes.*, *precommissura*; *pop.*, *postopticus*; *prop.*, *præopticus*.

1. The existence of the cranial flexure, but in a much less degree than in man.

2. The concomitant dorsal expansion of all the segments, giving to their mesal aspect the wedge shape which is simplest with the mesen.

3. The overlapping of the meten by the epen, and of the dien by the proen. The dien, in fact, occupied the excavation now bounded by the curved outlines of the fornix and the *fissura hippocampe*.

4. The complete circumscription of the *cœlie*, by the continuity of the endyma (indicated by the heavy black line), excepting at the caudal end of the metacelia ("fourth ventricle"), where, notwithstanding my prejudice to the contrary, I was forced to admit what seems to be a natural orifice in the metatela.

5. The large number (more than twenty-five) of important parts, in addition to the cerebral fissures, which are thus exposed by a mesal hemisection of the brain.

The large size of the medicommisura, and the concomitant reduction of the diacelia.

6. The non-visibility of the porta (*Foramen Monroi*), when the mesen is perpendicularly viewed; its position coincides very nearly with that of the level of the crista.

7. The slenderness of the mesocelia ("iter") and the small size of the epicle ("ventriculus cerebelli") as compared with the mass of the cerebellum.

8. The great difference between the two regions of the epicælian roof (cerebellum and valvula), which are, nevertheless, distinctly continuous.

Trusting that you will permit me to defer further discussion of encephalic nomenclature until the closing lecture,* I shall, when the use of names will save time and avoid circumlocution, designate the five encephalic segments by

* In the last lecture will be given a list of the technical names employed, with their synonyms and the abbreviations which are placed upon some of the figures.

abridgments of the general names more commonly employed: *Meten*, *epen*, *mesen*, *dien*, and *proen*. The cavities will be called *cælia*, and the cavities of the several segments christen themselves respectively *metacælia*, *epicælia*, *mesocælia*, *diacælia*, *procælia*, the shorter and simpler English form being mesocele, etc.; and in like manner we have *diatela* and *metatela*, *diaplexus* and *metaplexus*, etc.

In the brain of the adult mammal (Fig. 14) the cavities are small, especially those of the *epen* and *proen*; but, as shown in Figs. 15 and 16, in the fœtus, even of man, and at a stage considerably later than is represented in Figs. 2 and 3, the epicæle and proceles are comparatively large, and Tiedemann characterizes the fœtal mesocele (which is afterward so much contracted) as a "vast and spacious cavity."

FIG. 15.—CAUDAL ASPECT OF THE EPEN (CEREBELLUM, etc.) OF A HUMAN FÆTUS; $\times 2.3$. Drawn by Professor Cleaves. This shows the large size of the epicæle *a* compared with its parietes; the existence of lateral prolongations of the main cavity; the division of the dorsal aspect of the cerebellum into two lateral elevations separated by a mesal furrow; the existence of a thin caudal margin to which, presumably, was attached the *metatela*, and which may be represented in the adult cat's brain (Fig. 14) by the lobe just caudad of the epicæle.

The diagrams should almost explain themselves, but some general commentaries are desirable.

FIG. 16.—RIGHT CEREBRAL HEMISPHERE OF A HUMAN FÆTUS, about 4 cm. long; $\times 1.5$. Drawn by Professor Cleaves. This shows the large size of the cavity; the nearly uniform thickness of the parietes; the extent of the plexus; the early formation of the hippocampus ("hippocampus major") as a folding of the entire thickness of the medicornual wall; the commencement of the fissura Sylvii as a shallow fossa; the slight differentiation of the postcornu.

A complete and satisfactory series of diagrams of the development of the human brain will require material which, from the nature of the case, is not obtainable to order, and this material must be most carefully preserved and skillfully examined. Some of the stages, however, are fairly well known, and, as other writers on the subject have not refrained from describing the successive steps, I have ventured to substitute outline diagrams for words, and, in accordance with the first proposition on p. 145, the various kinds and locations of the stages of development are illustrated upon separate diagrams.

As compared with a description, a diagram has both an advantage and a disadvantage: it is more readily comprehended, but whatever is shown at all must be shown distinctly, and without the vagueness and qualification which would often more fairly embody our ignorance upon a given point.

For example, in several of the diagrams is represented the mode of formation of the entocælian plexuses. While

there is no doubt whatever that each plexus consists of a pial prolongation covered by the reflected endyma, the nature of the prolongation is less easily determined, and may, indeed, differ in different animals or in different parts of the same brain. This uncertainty is indicated by differences between the several diagrams, but on each figure it must be one way or the other. The only absolutely certain point is that *whatever is intruded is covered by the endyma, so that there is practically no interruption of the parietes*. So, too, the mode of introduction of the *callosum* and establishment of its connection with the fornix are not yet fully known. Again, since the several encephalic segments must be given some visible shape, that of the *sphere* has been selected as conventional and least objectionable, and probably true to nature in some cases or at certain stages.

While so far from satisfactory that considerable changes have already suggested themselves to me, and whoever uses them will see where improvements might be made, yet I can conscientiously recommend them to any one who is willing to make use of such a "labor-saving machine" as he would of a "working hypothesis" in advance of the demonstration of its accuracy in all details.

Since in the embryo and in the adult *Necturus* the encephalic parietes are of approximately uniform thickness, in those diagrams which represent only the forms and relations and modifications of the *cavities* the walls are omitted altogether.*

FIG. 17.—Six diagrams illustrating as many stages in the development and differentiation of the human cælie. To avoid complexity, the lateral diverticula of the dien (optic vesicles) and mesen (optic ventricles) are not shown; see the early part of this lecture, page 146.

A. The three primary cerebral vesicles.

B. The five secondary cavities developed therefrom. The middle remains unchanged; the posterior segments to form the metacæle and epicæle, and the anterior either protrudes or segments to form the diacæle and mesal proceles.

C-F. These represent the changes of the proceles, from a primitive mesal cavity, into one mesal (*aula*) and two lateral (*cellæ*) connected by the porie, and the subsequent differentiation of the rhinocele and the three cornua.

An encephalic cavity (*cælia*), like a mass of protoplasm,

* The diagrams (Fig. 17) were drawn by Professor Cleaves,

may partially subdivide (segment), may protrude symmetrically (bud), or be irregularly prolonged (cornua); Fig. 17.

One segment may be inordinately developed so as to overlap others in one or more directions (Fig. 19, A), and

FIG. 18.—The parietes are here introduced and shown by uniform thickness. The trans-section C is squared in order to carry out the analogy between the encephalic segment and a room with floor, sides, and roof.

its floor may become intimately connected with the roof of a segment so covered.

FIG. 19.—Here are illustrated the changes in the relative position of the segments.

A. One segment protrudes above another so that both are included in the trans-section B.

C. The entire series is flexed upon itself as in the human embryo (Fig. 1).

The entire brain may be bent upon itself (cranial flexure) (Fig. 19, C), or an elongated protrusion (cornu) may be bent (postcornu), or even bent and twisted also (medicornu).

FIG. 20.—A-D. Diagrams illustrating the degrees and modes of parietal thickening so as to reduce the cavity of a segment or modify its form. E, the wall has disappeared at one point.

The walls (parietes) may be thickened (hypertrophied) (Fig. 20) regularly or irregularly, and even to the extent of nearly or quite obliterating the cavity.

FIG. 21.—TWO MODES OF PARIETAL CONVOLUTION. A, the entire thickness is involved, as with the roof of the mesen in some animals, a certain cerebral fissure; B, the surface is thrown into folds and furrows by superficial outgrowths, as with most cerebral fissures.

In the diagrams already given (Figs. 18-24) the parietes are represented as if of homogeneous composition.

FIG. 22.—THE THREE KINDS OF TRANSVERSE COMMISSURES. A, a differentiation of the parietes, as with the postcommissure; B, a junction of apposed ectal (internal) surfaces, as with the medicommissure; C, a junction of apposed ectal surfaces, as with the callosum.

In reality, however, there are, in addition to the proper nervous walls, membranes and blood-vessels (Fig. 25).

The lining is the epithelial layer, ciliated in part at least, called endyma or "ependyma"; the immediate sheath

FIG. 23.—A tube is supposed to be twisted upon its long axis so that four points upon the same line are at as many different levels upon trans-sections. Such a twist occurs with the medicornu, by which the edge of the *Columna fornicis*, and of its continuation, the *fimbria*, comes to have different positions relatively to the lumen.

is the pia, which is vascular; and ectad of this is the arachnoidea. The pia follows the surface irregularities closely, but the arachnoidea crosses the depressions.

FIG. 24.—A tube like that which is given in Fig. 21 is supposed to be not only twisted, but coiled upon itself as the human medicornu is.

The walls may be thinned (*atrophy*), or disappear so as to leave at a given point only the lining membrane (*endy-*

ma) and the vascular sheath (*pia*), constituting a *tela* (Fig. 27, C).

FIG. 26.—DIAGRAM SHOWING THE RELATIONS OF THE ENDYMA AND THE PIA TO THE UNDULATIONS OF THE WALL.

Along a line of atrophy of the proper wall a fold of pia, or a vascular loop therefrom, may push before it the endyma, and thus project apparently into the cavity so as to form a *plexus* (Fig. 28). Strictly speaking, however, neither the pia nor its vessels are in the endymal cavity in any other sense than a kidney or the intestine is within the cavity of the peritonæum.

The parietes may be corrugated so as to form ental elevations (*hypocampa*, *calcar*) (Fig. 31), with corresponding de-

pressions (*fissura hypocampæ*, *F. calcarina*), or, without corrugation of the entire wall, there may be formed superficial ridges (*gyri*) and furrows (*fissures*).

FIG. 27.—The upper figure represents a tube (medicorua) along one side of which the parietes differ as follows:

- A. For 1-2 cm. from the tip (in man) the cornu has thick nervous walls.
- B. Here, for a short distance (2-4 mm.), the proper nervous wall is quite thin, and presently disappears altogether, leaving only the lining endyma and the sheathing pia, as at C.
- D. The membranes are torn away, and only their torn edges appear, the line of rupture constituting a *ripa*.

Between the lateral walls may be developed bands of transverse fibers (*commissures*) (Fig. 34), either (A) in the pre-exist-

FIG. 28.

FIG. 29.

FIGS. 28 and 29.—Diagram illustrating the presumed mode of formation of a plexus, by the intrusion of a vascular fold of pia or of loops of blood-vessels from the pia at a point or along a line of abrogation of the proper nervous parietes. At the left of Fig. 29 both membranes are shown distinctly; at the right, they are so closely applied to the vessel that the endyma constitutes merely a surface.

ing wall (*postcommissura*, *Commissura habenarum*, and *præcommissura*), or (B) under the floor (*pons*), or (C) between the opposed lateral walls directly through the cælia (*medicommisura*), or (D) between the contiguous walls of two adjoining masses (*callosum* and *Commissura fornici*).

The remaining diagrams (Figs. 35-39) are designed to illustrate some of the presumed steps in the formation of the two great cerebral commissures, the *Commissura fornici* and the *callosum*. Whether or not all the stages actually exist, such a series as this will at least facilitate the com-

prehension of the relations of these commissures to the other parts of the adult brain.

FIG. 30.—Four diagrams illustrating the presumed stages of formation of a simple plexus, that which hangs within the porta or "Foramen of Monro."

A definition and description of the fornix will be attempted farther on; for the present, to avoid misunder-

FIG. 31.—SCHEMATIC TRANSECTIONS OF THE THREE PROCELIAN CORNUA IN THE ORDER OF THEIR COMPLEXITY

- A. Into the postcornu projects a ridge (calcar or "hippocampus minor"), and on the mesal aspect of the occipital lobe is a corresponding furrow (*Fissura calcarina*).
- B. In the præcornu are an elevation, *striatum*, and an ectal furrow, *F. Sylvii*, but at the bottom of this furrow is an ectal elevation, the *insula*.
- C. The third degree of complexity is presented by the medicorua. Here the ental elevation is the *hypocampa*, "hippocampus major," and the furrow the *F. hypocampæ* or "hippocampal fissure." There is also an abrogation of the proper nervous wall along a line, the *rima*, for the admission of the proplexus, and the borders of the interruption are known, respectively, as *fimbria* and *tænia*.

standing, it may suffice to say that what is commonly called *fornix* seems to be only the result of the union of the parts

of the proccedian wall known as *hypocampa*, *fimbria*, *Columnna*, etc., which exist in each hemisphere, along the

FIG. 32.—The upper figure represents a mesal hemisection of the complete series of five encephalic segments. The forms are spherical, and the parietes of uniform thickness, excepting at the attachments of the remarkably constant dorsal conarium and ventral hypophysis. The lower figures (A-F) represent transections of the several segments, including the myelon.

mesen by a thin new formation, the *Commissura fornix*. The *lyra* is simply a part of the ventral aspect of the vaulted mass thus constituted.

FIG. 33.—Represents the principal locations of thickening and folding of the parietes. In the upper figure, the conarium (cn.) is crowded caudad by the superposed hemisphere, and the ridge which is left at each side is the *habena*, as seen in A. B represents the dorsal aspect of the modified mesen, which in mammals presents a transverse as well as a longitudinal furrow, and hence is sometimes called *corpus quadrigeminum* instead of *corpus bigeminum*.

In the lower portion of each figure both hemispheres are represented, but in the upper only that of the right side appears. Properly, its mesal surface should be shaded and the porta should be indicated, but neither of these features is essential to the recognition of the points especially involved.

In Fig. 35 the hemispheres are connected only by the *terma* and other parts of the aulic parietes. Along the ventro-mesal margin of each hemisphere is a thickening, indicated in the upper figure by the dotted line. This thickening is continuous with the thickened dorso-cephalic margin of the porta (*Columnna fornix*).

In Fig. 36 a junction of the two hemispheres occurs along this thickened line, but the lamina by which this junction is effected (*Commissura fornix*) is very thin, much thinner and also much narrower than could be well shown upon small diagrams.

In Fig. 37 the apposed mesal surfaces of the hemispheres are united by a second new formation, the *callosum*.

As a whole, the callosum is dorsad of the *Cs. fornix*, and the caudal ends of the two are eventually, if not primarily,

FIG. 34.—The simplest idea of the three kinds of transverse commissures is indicated in Fig. 22. In Fig. 34 an attempt is made to show them in connection with the parts which they unite. In the upper figure the dotted areas represent the cut ends of the fibers which appear as lines in the transections below. The medicommissure is made to look like the rest, although probably it is more cellular than fibrous. The commissure just cephalad of the hypophysis is the chiasma, and no transection is given at that point. The praecommissura is represented in horizontal section in order to show not only that it unites the striata (which are really but thickenings of the proccedian wall), but also that it is a differentiation of the *terma*, the cephalic boundary of the aula. The dotted line on the shaded mesal surface of the hemisphere indicates the outline of the proccelia, and its two undulations exemplify the mode of formation of certain cerebral fissures by corrugation of the entire thickness of the wall. The other elevations and depressions, like those of the cerebellum, are comparatively superficial.

continuous at the *splenium*. That part of each hemisphere wall which is thus intercepted between the callosum and

FIG. 35

FIG. 36

the *Cs. fornix* becomes (or remains) thinner than the rest, in man at least, and the two delicate laminae thus formed

FIG. 37

constitute the *Septum lucidum*; each lamina is a *hemiseptum*, and the space between them is the pseudocœlia or "fifth ventricle."

Fig. 38.

In Fig. 38 the *endyma* and *pia* are introduced; the two contiguous layers of *pia* which respectively lie ventrad of the fornix and dorsad of the thalami (*dien*) together constitute the *velum*.

In Fig. 39 the *arachnoidea* is shown bridging the interval between the hemispheres, etc., leaving a *subarachnoid space* (*sa.*) between it and the *pia* at these places.

Fig. 39.

Finally, in Fig. 39 are represented the intrusions of pial prolongations constituting the *plexuses*. The line of abrogation of the proper nervous wall for the admission of the *proplexus* is the *rima*, and its borders are the *tenia* and *fimbria*.

A section showing the actual relations of the parts here represented will be given in connection with the third lecture.

MEDICAL DEGREES IN FRANCE.—During the academic year 1882-'83 six hundred and seventy-two M. D. degrees were conferred in France. Not far from three quarters of the whole number, or four hundred and sixty-five, were conferred by the Paris faculty. Montpellier comes next with sixty-nine; then follow Bordeaux with forty-six, Lyons with forty-three, Nancy with twenty-one, and Lille with twenty.—*Medical Times and Gazette*.

THE COST OF ERGOTIN.—The "*Medical Times and Gazette*" states that the ergotin prepared by Gehe & Co., of Dresden, is the most costly pharmaceutical preparation in the market, a gramme costing 200 marks, or about \$48 of our money. At this rate, an ounce would cost about \$1,492.80.

Original Communications.

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.

By FORDYCE BARKER, M. D., LL. D.,
PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE.

(Concluded from page 153.)

Before leaving this part of the subject now under discussion, I will briefly allude to one other point, which strikingly illustrates the difference between puerperal fever and septicæmia. I think there can be no doubt that the majority of the profession believe that all those causes of nosocomial malaria, such as aggregation, bad ventilation, contact with septic material, etc., which have a tendency to induce septicæmia in surgical cases, have an equal tendency to develop the disease known as puerperal fever in women recently confined. But this does not prove that the diseases are identical, for I think there is abundant evidence that, while these causes are always requisite for the development of surgical septicæmia, puerperal fever may be a very epidemic when these causes are wholly wanting.*

In the early months of 1873 puerperal fever prevailed in the best parts of the city, and in that class of society possessed of abundant means and living under as good sanitary conditions as are possible in any large city, to a degree and extent here unknown for the previous twenty-five years. The deaths from this disease in the hospitals and in the wards of the city where the poor are aggregated were much fewer than in many former years. In five of the best wards of the city, in which are the residences of a great proportion of those of wealth, and few of the class of dwellings known as tenement-houses, with a population of 307,046, there were 80 deaths from puerperal fever, while in the remaining wards of the city, with a population of 605,245, there were but 63 deaths. In other words, I may say that during this period, in those wards of the city where the causes of septicæmia must have existed in the greatest abundance, the mortality was nearly one third less from puerperal fever, in proportion to the population, than in the best parts of the city, where these causes of septicæmia could have existed only in a very limited degree.

I have good cause to remember this epidemic, as the excessive work, mental strain, and loss of sleep which it brought upon me, as my medical friends know, affected my health to a degree that required nearly six years for perfect recovery. I saw ninety-five cases during this epidemic, of which nineteen were fatal. Most of the latter I believe to have been fatal in their character from the history which I received, and I only saw them once. I had three cases in my private practice, in one of which the patient died. After this, most of the ladies whom I had engaged to attend, by my advice, went out of town for their confinement, and all these had normal convalescence.

From all these considerations, I think that if all the knowledge of this disease be derived from authors who have studied it in hospitals exclusively, it will be limited and one-

* See "Puerperal Diseases," by Fordyce Barker, Appendix, p. 516.

sided, and the deductions, both as to its pathology and as to its treatment must in many instances be erroneous and unsafe. Especially must this be the case with those whose well-deserved eminence as operators compels them to be brought in frequent contact with surgical septicæmia and to witness the terrible results which this produces after the most skillful performance of such operations as laparotomy and ovariectomy. Indeed, one can hardly understand how such a surgeon, who accepts the theory and believes in the necessity of such a prophylaxis and such treatment as is insisted upon in the paper under discussion, would ever dare to enter the room of a puerperal woman.

There are many other details in this connection which I am tempted to discuss, but these will doubtless receive due attention from the speakers who will follow me. I will, therefore, content myself by expressing an opinion which will surprise many who have been carried along by the popular wave of the septic theory as the initial cause of most of the puerperal diseases. My conviction is strong, based partly on individual experience, but chiefly on a careful study of the clinical midwifery reports of private practice and all the literature of the subject in my possession—and this is very full as regards the English and French languages—that, outside of hospitals, less than two per cent. of the puerperal diseases and not half of one per cent. of the deaths after childbirth are due to septicæmia. There are no statistics of private practice which demonstrate the error of this opinion. The belief of the septicæmists that terrible dangers threaten every woman in childbirth is based wholly on theory. Because the maternal system has certain peculiarities differing from its normal condition—because the lochia are a poisonous fluid—and because there is always a certain amount of traumatic lesion in the parturient canal following parturition, every child-bearing woman incurs a most hazardous risk. This is a blunt statement of the argument and its deductions.

I do not care to summon in support of the opinion that I have just expressed any higher authority, even if it were possible to do so, than the writer of the paper which we are now discussing and from which I make the following quotations:

"And yet what are the usual results? Recovery, uniformly, I might say universally, unless some unusual occurrence manifests itself to prevent this happy consummation. Theorizing about the matter, one would suppose that the mortality resulting from such a state of things must be excessive."

"And yet the facts are these: only about one or two in every one hundred parturient women ordinarily die when properly cared for during labor, even in public hospitals."

Now, if we recall the fact that a large proportion of deaths from childbirth result from the casualties of labor, such as convulsions, rupture of uterus, hæmorrhage from placenta prævia, nervous shock, etc., it will be seen that the belief which I have expressed differs but slightly, if any, from his. I certainly find it much more agreeable to refer to our points of agreement than our points of difference.

The limit of time which, in justice to others who follow,

I have allowed myself will permit but a very few remarks on "the prophylactic measures which should be adopted in all midwifery cases, whether they occur in hospital or in private practice," as the author of the paper distinctly avows. If "she who is about to bring forth" must "be treated as one about to go through the perils of a capital operation"; if all those preparations, so definitely enumerated, which gynecological surgeons insist upon previous to an ovariectomy or a laparotomy, are necessary in ordinary labors; if the danger from child-bearing be so great that a wise and prudent obstetrician is justified in subjecting his patient to the hazardous depression of intense anxiety and fearful doubt as to results, and in surrounding her with the vivid apprehension of her family, instead of stimulating and cheering her with the great happiness of maternity and the hope of increased interest and love from her husband; if all or even a considerable part of the details mentioned are necessary "to save thousands of lives which are now lost," and to spare "thousands of desolate households the sorrow of losing their female heads"—then it seems to me evident that the State should make child-bearing a penal offense for all those families who do not have a sufficient annual income to make it possible to carry out all these requirements. Such a law could only be made effective by adopting the facetious suggestion, which appeared in the "Medical Record" of January 19th over the signature of Seth Hill, Stepney, Conn., making it compulsory for all women unable to carry out these requirements "to wear an antiseptic pad over the vulva from the inception of the catamenia until the menopause, to be non-removable without strict antiseptic precautions under the carbolic spray"; and, to secure this pad, it would be necessary that some State official should apply the lock, which, no doubt, many present have seen in the Museum de l'Hôtel de Cluny, said to have been used by the noblemen of France to prevent their wives from falling during their absence in the Crusades.

The description given of puerperal fever, true as it may be, in its outlines, of the septicæmia which gynecological surgeons are so often forced to encounter, I think, will strike obstetricians familiar with the disease in the lying-in chamber as the ideal picture of a poet, differing as much from the scientific description of trained clinical observation as the pictures of natural scenery by a Byron or a George Sand would differ from a scientific description of a mountain or a lake by Humboldt.

As to diagnosis, I can not regard the symptoms mentioned, even in their totality, as pathognomonic of septicæmia, as all of them are to be found in other puerperal affections, when there is no evidence of septic absorption, unless with the author it be assumed that all puerperal disturbances are due to this cause alone. It is made an important point by the author to determine whether "the septic disease which is developing has originated in wounds situated between the os internum uteri and the vulva, or in the endometrium, above the former point." He says that "usually the question has to be decided by the efficacy or inefficacy of frequent germicide vaginal injections in bringing down the temperature and controlling other grave symptoms."

Now, I look at this subject from an entirely different point of view, and, as I have not the time to examine in detail the treatment inculcated in the paper we are now discussing, I must be content with the expression of my convictions by a few general propositions.

In puerperal fever, as met with in private practice, we have to treat the *consequences* of some form of blood-poisoning. This may or may not be septic poisoning. In private practice, I think it generally due to some occult, possibly atmospheric, epidemic influence; in hospital patients, nosocomial malaria, often associated with septic poisoning.

No treatment which interrupts the normal physiological processes—such as the retrograde metamorphosis of involution, the fatty transformation of the component fibers of the uterus, or the cicatrization of its internal surface by the exudation of organizable lymph, and the development of a new layer of mucous membrane, or the healing of traumatic lesions—can be justified, unless positive symptoms, now well understood in science, demonstrate their necessity.

Antiseptic injections, both vaginal and intra-uterine, are of great service when the indications for their use are clearly shown by local signs or general symptoms, but they can not be recommended with safety as a routine practice on theoretical grounds, as, for obvious reasons, they may be most detrimental in retarding the cicatrization of lesions and the other processes of normal convalescence, and are otherwise sometimes dangerous. In several cases which I have seen with others, where antiseptic injections, both vaginal and intra-uterine, had been used with all the care and precautions inculcated by the author and kept up for several days, the temperature rapidly fell, the profuse and sometimes offensive vaginal discharges speedily diminished, the pulse and general condition manifestly improved after the injections were discontinued.

I will only add a few words in regard to refrigeration as a means of reducing fever in puerperal diseases. I have no question that it may be useful in some cases, but my own experience in this method of treatment has not been favorable. Many years ago I tried it in several cases in Bellevue Hospital, but I soon gave it up, as the results were less satisfactory than where other plans of treatment were pursued, and I know that this was the conviction of my house staff. Cold will effectively and usefully reduce the temperature in active inflammations and acute fevers, but in adynamic diseases and in hectic fever this must be attended with a rapid waste of tissue more dangerous than the pyrexia. In three cases which I have seen with others—two a year ago and one this winter—where the coil had been assiduously kept over the abdomen, most of the time two or three days, the conditions in each were remarkably similar. The abdomen was blanched, colorless, and not sensitive to pressure; the patients all avowed that the coil gave them great comfort, but the temperature was very high in all—in one 104.3° , and in the other two over 105° ; the pulse was very rapid and feeble, the heart's action extremely weak, with pulmonary symptoms—such as short, rapid, and shallow respiration—which caused grave apprehension that there might be latent centric pneumonia. After some discussion, I induced my friends to remove the refrigerating coil, and, in

its place, to cover the abdomen with flannel saturated with the oil of turpentine, for the purpose of stimulating vaso-motor action, restoring the capillary and equalizing the general circulation. All were taking quinine in large doses. This was greatly diminished or wholly stopped, and digitalis and ammonia in full doses were substituted. In a few hours the change in each of these cases was most remarkable; the temperature was reduced from two to three degrees, the pulse was greatly lessened in frequency and increased in force, and all pulmonary symptoms, which had caused so much anxiety, had disappeared. Two of these patients recovered and are still living. The third, who had also been treated by antiseptic vaginal and uterine injection, was apparently convalescent, when suddenly she became much worse; collapse supervened, which was found to be due to a sudden development of diphtheritic membranes which covered the mucous surface of the vulva and vagina, the result of carelessness and dirtiness of the nurse. The patient died in a few hours.

I now ask permission to refer to a matter outside of the question of the prevention and treatment of puerperal fever, but in behalf of the "truth of history." I ask any who may feel sufficient interest to turn to the 320th page of my work on the "Puerperal Diseases," where they will find on this and the following pages the subject of intra-uterine injections fully discussed. Instruments for this use, which had been devised more than fifteen years ago, were shown to the class, and explicit directions were given as to the methods and indications for these injections, differing in no essential from those we heard in this hall on the 6th of December. The lecture was delivered in the amphitheatre of Bellevue Hospital, in February, 1869, and the work in which it was printed was published in January, 1874. Then it may interest some to look at page 85 of Volume IV of the "Transactions of the American Gynecological Society," and read the papers by Dr. Edward W. Jenks, of Chicago, and Dr. James R. Chadwick, of Boston, on intra-uterine injections, and the discussion which followed.

In conclusion, I will only add that my creed to-day is fully avowed on page 476 of the book to which I have before referred, and, unless in the future I learn new facts and new arguments to change my faith, I shall "die impenitent."

After the reading of the paper, Dr. Barker said:

The subject is now open for general discussion. So many of the fellows of the Academy have signified their willingness to speak, and there are so many whom all will be anxious to hear, that I felt it to be a duty to limit my remarks in the paper just read to a very restricted time, and to content myself with the enunciation of such general principles as I believe to be important truths, without entering much into details.

But there is one point which I hope will receive attention from the speakers who are to follow. Very early in my practice I began to direct the use of vaginal antiseptic injections for the first week after labor, the antiseptic being Labarraque's solution. When I went on duty at Bellevue Hospital, now nearly thirty years since, this was made the

invariable rule in the lying-in wards. Subsequently carbolic acid was substituted, and I give a formula for its proportions in the work on "Puerperal Diseases." I have habitually directed its use in all my obstetric cases until the past two or three years.

At the time of the International Congress in London, in 1881, I happened to be seated at a dinner next Dr. Thomas Keith, of Edinburgh, and had a very interesting conversation with him as to the use of antiseptics in ovariotomy. What he said was very suggestive, and led to a good deal of subsequent reflection on my part as to the use of antiseptics in obstetrics. I recalled to mind the fact that often in my practice I had seen disturbances and interruptions of puerperal convalescence the first week after labor, and it occurred to me whether this might not be due to the carbolic acid; and the following autumn I decreased the proportion of the carbolic acid one half, and thought that my patients did better. On further reflection on the subject, I said to myself the carbolic acid, even in the larger proportions which I have formerly used, was not strong enough to destroy the micro-organisms. Is it not possible that Nature has wisely arranged to furnish the best fluid for constantly bathing the bruised and lacerated tissues of the parturient canal in the much-maligned lochia? Are not absolute rest and freedom from disturbance of these tissues much more favorable to their restoration than any washes that can be used? Since that time I have considerably surprised nurses by directing that no injections should ever be used unless specially ordered. It is scarcely necessary to say that absolute cleanliness was strongly enjoined, and that not a spot of blood, either on the bedding or on the clothing of the patient, should be found.

Dr. A. A. Smith, who frequently visits my patients when I have other engagements, during the first puerperal week, tells me that this direction was given more than two years ago. Since September, 1882, it is only in a small proportion of my obstetrical cases that I have seen any reason for ordering even vaginal injections, and Dr. Smith informs me that this is true of his own cases. We both can declare that since that, including even instrumental deliveries, we have not had a single case in our practice which during the puerperal period has given us any anxiety or required more than an ordinary attendance of one daily visit for nine days.

This may be only a happy coincidence, but it seems to me significant, and I think most present may like to hear the views of others on this new departure.

PHENIC ACID IN THE TREATMENT OF YELLOW FEVER.—In a recent number of the "Bulletin de l'Union des Sociétés françaises de New York" we find a letter addressed to the president of the *Académie des sciences*, of Paris, by Dr. de Lacaille, a French physician residing in Rio de Janeiro. The writer professes to have cured thirty-eight yellow-fever patients in succession by the use of Déclat's preparations of phenic and sulpho-phenic acids and the phenate of ammonium, using the latter in the gravest cases. He states that in the early stage of the disease it is sufficient to give the remedies by the mouth, but that the hypodermic method is necessary in those that are advanced. He contrasts these results with an experience of his own in 1851, and regrets that he did not then know of these measures.

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.*

By T. GAILLARD THOMAS, M. D.

CLINICAL PROFESSOR OF DISEASES OF WOMEN IN THE COLLEGE OF PHYSICIANS
AND SURGEONS, NEW YORK.

MR. PRESIDENT AND GENTLEMEN: When quite a young lad I was present at a murder trial which made a deep impression on my mind. When the case had been presented, the attorney for the commonwealth, who was a florid and rather bombastic orator, got up and made a speech of two hours. At its close all were very anxious to hear the counsel for the prisoner, who had a reputation for great eloquence. Judge of the surprise of the audience when he arose and quietly said: "May it please your Honor, the case is closed; I rest it here. The gentleman on the other side has made so able a speech in favor of my client that I rely upon it for his acquittal." The prisoner was acquitted. I feel very much in this way with reference to the paper of Dr. Barker, to which I have just listened with feelings which I know you, who are his well-wishers, fully share with me—feelings of surprise, regret, and sorrow.

Discussions such as this can not fail to do good, however, for I am a great believer in the old Latin adage, "*ex collisione scintilla*"; and although, in view of the very grievous errors which, according to my distinguished colleague, I have brought before the profession and suggested for its adoption, I may be preferring silver to gold in deciding in favor of speech instead of silence, I feel called upon to say a few words in simple self-defense, that first law of nature.

Our honored president has been very guarded in opening his attack upon my paper, and has seemed to feel concern lest its author should take offense at his sallies. Let me assure him and you that it would take a great deal more than such a discussion as this to weaken the ties of friendship which a quarter of a century has cemented between us, or to cause me to take exception to the criticism of one whom I have often, in times past, encountered in the lists of debate, and have ever found just, magnanimous, and courteous!

But alas! gentlemen, my adversary has to-night incautiously and, I think, unwisely ventured to use against me that dangerous weapon—a two-edged sword—ridicule. Right mercilessly has he given me one edge; let him beware of the other!

As I saw him draw and flourish this weapon a few minutes ago, I experienced mingled feelings of pleasure and of pain. In a scientific discussion, more especially in a debate which directly and immediately concerns the saving of human life, which at this very moment is being deplorably sacrificed among us, ridicule, elsewhere a powerful weapon, is the poorest and most pitiful of arguments! It is the resort of the weak, not of the strong; and, as my adversary

* Being the remarks made by Dr. Thomas before the New York Academy of Medicine, February 7, 1884, on being requested to close the adjourned discussion on his paper read before the Academy, December 6, 1883, and published in the "New York Medical Journal" for December 15, 1883, p. 649.

used it just now, I said to myself, "He feels himself to be very, very weak; he totters upon his pedestal; 'tis pity that he should feel so; for otherwise that master pen which so often in times past has enchanted us would not to-night emit what carries pain to my heart and to the heart of every true friend of his in this assembly, evidences of irascibility and of irritability which are so little characteristic of his real nature; otherwise I should not be able to recognize, as all others must do, the utter want of logic, the deplorable absence of argument, the total neglect of appeal to facts, and the very conspicuous presence of signs of wounded *amour propre* which unite to form an unwholesome stream that meanders through his essay.

I shall not detain you long. I have little to say, for Dr. Barker's attack calls for no rebuttal, and demands no argument on my part. I said all that I had to say on December 6th, when the original firebrand was thrown down and picked up by the wrong end by my excellent friend. There are, however, one or two points upon which I must touch to avoid misrepresentation.

Dr. Barker declares the pathology which I have advocated to be unsustained by even the most recent researches of those whom we recognize as guides; he appears to object to the fact that I have not stuck closely to the dicta of our text-books, and hugged to my soul the tenets of a by-gone time as he has done. This is hardly fair. I strove to follow the advice of Dr. Billings when he says: "Have something to say, say it, stop when you have said it." Had I had no opinions of my own to offer you, had a practice in a large metropolis and in great hospitals taught me nothing during a period of thirty years, I should not have appeared before you. Let my adversary inform himself upon the recent views of pathologists upon this subject, and he will find that it is his views which are effete, not mine which are jejune.

So far as I can gather anything certain from his discursive paper, the pivotal idea of Dr. Barker's attack seems based upon the belief that I regard the lochial discharge as a poisonous fluid, which, by absorption, by abrasions in the genital tract, gives rise to puerperal septicæmia. I need not tell you that no such absurd idea ever obtained foothold in my brain or enunciation from my tongue. If his idea be this, he has been guilty of very superficial reading of my paper, and should not so easily have concluded that I was affected by idiocy. Look at my essay, which is now in print, and you will see, what you already appreciate must be the fact, that I stated merely that the lochial discharge was a material ready to take on those alterations which are effected by micro-organisms of bad character, which, changing its nature, render it poisonous to the abraded tissues. I believe that you will find that the pathology which I have offered to you is abreast with the views of the advanced pathologists of Germany, France, and Great Britain. As to the pathology of my adversary, Dr. John Thorburn, of Manchester, England, very justly expresses concerning it, I think, the accepted view of the profession when in a footnote to an article upon "Metria," which appears in the "British Medical Journal" for August 11, 1883, he says: "It would be inexcusable not to make some reference to the

very able papers of Dr. Napier, in the 'Obstetrical Journal' for 1880, on puerperal fever. He, along with Fordyce Barker, defends the old position of a specific puerperal fever *sui generis*. The time limit imposed by our regulations allows no opportunity of consulting step by step such arguments as he adduces. I can only say that his invaluable collection of facts produces in me an opinion diametrically opposed to his own."

My critic upbraids me for want of thoroughness and for that sketchiness of detail with reference to my description of symptoms. I will merely say in answer to this that I intentionally assumed this style, as I was not preparing a lecture for a class of medical students, and that my paper was distinctly announced to be one upon "The Prevention and Treatment of Puerperal Septicæmia," and upon nothing else. I can not but thank him for his kindness in comparing my style in this sketchy description of symptoms to that of Byron and Humboldt (I believe these were the authors with whom he compared me), but, alas! as I recall the passages to which he alluded, I am pained to confess that the similarity of style does not strike me so forcibly as it does my too partial friend.

Here let me draw the veil of pitying silence over the unfortunate allusion to the squib of Stepney and the relics of the Hôtel de Cluny! We stand to-night upon ground consecrated to science by the dignified fathers of the New York Academy of Medicine, who have now passed away! We stand face to face with the terrible mortality which marks puerperal fever among us at this very moment!

And now, gentlemen, a few words as to the "prevention and treatment of puerperal fever," which is the only legitimate subject before us for discussion this evening; the only theme which should not at the very commencement of these exercises have been rigidly ruled out as irrelevant by our president.

How difficult is it in a large body like this to keep a discussion properly directed to the points at issue! The crucial questions, Fellows of the Academy, which are before you to-night are these: 1. Are you to look upon puerperal septicæmia as a poison due to the development of micro-organisms, and are you by every means in your power to guard against the contact of these with the genitalia of the puerperal woman? 2. When the disorder is developed, is it best for you to keep your patient semi-narcotized and quininized, while the distended abdomen is covered with stupes of turpentine or poultices, and await the result, as has formerly been done; or are you to seek to counteract the septic process which has invaded the genital tract, by local applications? These are the momentous questions; the other points are non-essential ones, and, although important in some respects, sink into insignificance when compared with them.

Take, for example, the first of my suggestions as to cleansing the lying-in room and applying antiseptic solutions to its walls and floors before labor sets in. This seems to appear to some like one of the labors of Hercules, and a very valued friend of mine, one of the most eminent obstetric professors of this city, seems so firmly to keep his eyes fixed upon it as to allow it to draw his gaze away from oth-

ers which are of tenfold its value. Now, gentlemen, what is really the difficulty in doing this thing? In the cottages connected with the Woman's Hospital it is regularly done whenever a new patient comes in for laparotomy, which is, on an average, once a week; and whenever I operate in private practice, let the operation be as trivial as it may, I always insist upon its performance. A scrubber, and there are many women in New York who make such work a business, takes up the carpet and sends it to the naphtha cleaning works or replaces it by rugs; she then scrubs the floor and furniture with a solution of carbolic acid or the bichloride of mercury. Then, covering a broom with a towel, she stands upon a pair of steps, and, dipping this in a bucket, she wipes off the walls and ceiling. The whole work of cleaning a chamber occupies a few hours. Dr. Lusk has said that he has never seen any good come from scrubbing furniture with an antiseptic solution—agreed; I have never seen it do any harm, and until I do so I shall feel that it is safer to resort to it. But, I assure you, I am not particularly enthusiastic about this cleansing of the chamber, nor do I regard it as by any means essential. If any one prefers to have his patient confined in a dirty room rather than a clean one, let him do so by all means; I do not gainsay it. If I need any defense for having pressed the claims of cleanliness in this regard, let it be found in the fact that he who offers rules for a system must aim high, not low; that, aim as high as he may, many will fall below the standard, and that, if a low level be assumed, no one will go above it and take a higher.

My second suggestion for prevention has reference to complete change of clothing, and the taking of an antiseptic bath by doctor and nurse before taking charge of a lying-in woman, if they have knowingly been exposed to the effluvia of septicæmia, erysipelas, scarlet fever, typhus, or any similarly contagious affection. Will any one object to this as unnecessary or impracticable? I think not. Yesterday, at 4 P. M., I saw in Stamford a very bad case of puerperal septicæmia; this afternoon, at 3, I performed Tait's operation in a very important case which could not be delayed. I ventured to do this only under these circumstances: this morning I took a hot bath of water strongly impregnated with salt, and after it shampooed my hair and beard thoroughly with a saturated solution of boric acid, scrubbed my hands thoroughly, by means of a nail-brush, with a solution of the bichloride, 1 to 1,000, and changed every article of clothing which I had worn at the moment of exposure. The trouble was not great, nor was the process a disagreeable one. It may have done no good whatsoever, but I feel sure that it did no harm, and it certainly quieted my conscience and gave me a feeling of comfort that I could have obtained in no other way.

My third suggestion was that during labor a warm antiseptic injection should be administered to the patient by the nurse about every four hours, and that a towel wrung out of this warm solution should be laid over the vulva. Who objects to this? "If any, speak, for him have I offended." It is very soothing to the patient, and it is difficult to see how she could be injured by it.

My fourth suggestion merely relates to cleanliness of

the hands on the part of doctor and nurse. The propriety of this I will not discuss.

No one will quarrel with my fifth and sixth, which merely require the physician to attend intelligently and faithfully to the performance of the third stage of labor, and the examination for and closure of wounds about the vagina and ostium vaginæ.

I now come to the seventh suggestion—the use of vaginal injections every eight hours, beginning eight hours after delivery. The arguments which have been brought up against this practice since I read my paper have had great weight with me; I confess that I feel less firm in my convictions upon this point than I did, and that in future I shall examine the question carefully before I determine to adhere to my plan. You may ask, Why this change of opinion? My answer is that I strive to mend the fault of yesterday with wisdom of to-day.

The rest of my rules will be so certainly agreed in that I can not question the concurrence of all, even of the eminent gentleman our president, who regards my efforts as so hurtful to progress and so damaging to the health of the community to whose medical guides I have made appeal.

A few words now, before closing, upon some of the means which I have suggested as to treatment. With reference to my present views upon the use of cutaneous refrigeration for the controlling of high temperature, however produced and in the course of whatever disease occurring, I would, after a very extensive experience, say this: Were the laws of my country to prohibit a resort to this method, I would be unwilling to continue the practice of my profession, for I could not do so relinquishing what I sincerely believe to be one of the most valuable therapeutic resources at the disposal of the physician.

With regard to intra-uterine injections, I fear that I have expressed myself in such a way as to allow it to appear that I resort to them with very little provocation and upon all occasions when hyperpyrexia supervenes after childbirth. No impression could be more erroneous. No one could have striven more than I have done to keep within proper bounds the indiscriminate use of this valuable but dangerous resource. Let me illustrate my feeling with reference to this subject in the following way: I believe that the operation of trachelorrhaphy, as introduced by my friend Dr. Emmet, is one of the greatest advances which a quarter of a century has seen in gynecology. I believe that at the present moment it is doing a great deal of harm on account of its indiscriminate and too frequent performance, many seeming to believe that every woman who bears a child requires a resort to it. Does this militate against the great value of the procedure? Not at all. "*Uti sed non abuti*" might well have been written over its original description, as in olden times it was inscribed upon the case which held the lancet.

My friend Dr. Barker must here allow me to offer him a most full and sincere apology for not having accorded to him in my paper the credit which was his due in connection with the introduction of intra-uterine injections into obstetric practice. I know that he will freely forgive me when I state that the omission was due to ignorance on my

part of the facts which he has stated to-night, and not to any intentional neglect.

Dr. Mundé has expressed the opinion that I have not sufficiently guarded my readers against the dangers of intra-uterine injections. As I recall my statements I can not but feel that he is in error upon this point. I certainly strove, to the utmost of my capacity, to so depict these dangers as to put every man upon his guard concerning them.

I have not been surprised to notice, among other criticisms of the preventive measures which I have suggested, a tendency on the part of some to ignore the necessity for them, especially in private practice. That this would in all probability be done I suggested in my paper, and I came here this evening prepared to use some statistics which would invalidate this position. I shall not use those that I brought, however, but employ in their stead some which have been offered by the speakers of this evening. Dr. Hanks declares that 250 women died from puerperal septicaemia in this city last year; that is 250 to 1,000,000 inhabitants. The United States probably contains in round numbers 40,000,000 inhabitants, which would give us 10,000 deaths in one year, and in twenty years, which is about the average child-bearing time of women, 200,000 deaths. Surely this looks as if something should be done to lessen the mortality of this disease. Does the plan which I have suggested accomplish this result? Let Dr. Lusk answer. He has just told us that in Prague, before a similar plan was adopted—that is, before antiseptic midwifery was introduced—they lost five per cent. of hospital puerperæ by septicaemia; since then 1,100 women have been delivered without a single death. I hope that I am correct in my quotation of Dr. Lusk; I think that I am—no death, against fifty-five in former times!

And now methinks I hear a whisper to this effect: "These are the statistics of hospitals; the disease must be rare in private practice, for does not Dr. A. tell us that he, out of 500 cases, has had no deaths; Dr. B. that out of 1,000 he has had none; and Dr. C. that out of 1,500 he has met with only one." Patients are constantly dying from this cause in private practice, nevertheless. It is now just two months since I read my paper, and during that time I have been called to five cases of puerperal septicaemia, four of them, at least, in the higher walks of life, and all four of the most desperate character. I prefer to state with whom these patients were seen, and I feel sure that my colleagues who called upon me will appreciate my motive and pardon me for doing so. The first case I saw with Dr. Glück and Dr. Kucher; the second with Dr. Hutchison, Dr. Crane, and Dr. Paine, of Brooklyn; the third with Dr. Lyons, in which suppurative synovitis and abscesses had followed a miscarriage; the fourth I was called to by Dr. Loewenthal, but could not attend; and the fifth I saw yesterday in Stamford, with Dr. Janeway, of New York, and Dr. Phillips and Dr. Hurlburt, of the former place.

I have ventured to give the names of the practitioners with whom I saw these cases, to prove that they occur even under the most favorable circumstances as to social surroundings and medical care.

And now, gentlemen of the Academy, let me thank you for the kind and courteous attention which you have given

me: It is that attention and that courtesy which have emboldened me to detain you so long. I feel very sure that you will give full credence to two statements which I make in bidding you good-night: *First*. That I have no wish to be dogmatic and uncompromising in reference to the rules which I have suggested for the prevention and treatment of puerperal septicaemia. *Second*. That if venom has seemed to flow from my tongue it has not reached it from my heart, which has been entirely free from it; and that if I have seemed to strike too trenchant blows at the honored head of our president, I have struck purely in self-defense at one for whom I yield to no man in respect, admiration, and affectionate regard.

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.*

By WILLIAM THOMPSON LUSK, M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN THE
BELLEVUE HOSPITAL MEDICAL COLLEGE, ETC.

I THINK the Academy is to be congratulated upon two such papers as that of the evening and the one of December 6th, as, in many ways, in spite of seeming antagonisms, they really in a measure supplemented each other.

While it is my desire to confine my remarks to the local treatment of puerperal fever, yet I will venture to state my faith concerning the ætiology of the disease, as in practice every man is governed by his theoretical views. I would say that, in my opinion, surgical fever and puerperal fever are not simply analogous, but are essentially one and the same process.

To maintain this definition it is, however, necessary to bear certain facts in mind. Much confusion has been occasioned by the failure to classify as distinct from puerperal fever the action on the puerperal woman of certain extraneous poisons, such as those of scarlatina, of typhoid, and malaria, which are so modified by the puerperal state as to lose some of their characteristic features, and to present many of those usually attributed to puerperal fever.

Again, certain differences in the symptoms of surgical and puerperal fever are due to differences which are purely anatomical. The entrance of poisons into the system through a clean-cut stump necessarily would be attended by phenomena somewhat different from what would be produced by the same poison when introduced through a puerperal wound, where the serous infiltration of the tissues, the wide interspaces, the dilated lymphatics, and veins—all constituting the ordinary machinery for the removal of retrograde products of the pelvic organs during childbed—are equally active in conveying deleterious as well as normal materials into the organism.

Again, it should not be forgotten that in puerperal women a special danger exists in the proximity of the peritonæum to the seat of infection.

But, even where differences in symptoms are not explicable upon anatomical grounds, we still find surgical and puer-

* Being, with additions, remarks made before the New York Academy of Medicine, February 7, 1884, in the adjourned discussion on Dr. T. Gaillard Thomas's paper.

peral fever linked together by the presence of the round bacteria. Both diseases are of septic origin. Many of the arguments against the septic nature of puerperal fever are based upon a confusion of terms and the failure to recognize the modern distinction between putrid intoxication and septicæmia proper. A decomposing fluid, containing rod-like bacteria alone, is characterized by foulness, and, injected into the veins, produces symptoms resulting from disturbances of the nerves, the blood, and the chylipoietic system; but, unless the injection be large or frequently repeated, the animal experimented upon, after a period of prostration with fever and stinking diarrhœa, recovers. This form is not inoculable, because the rod-like bacteria under no circumstances thrive and multiply in the human system, and this explains the fact that physicians have been able in some cases to pass from the dissecting-room to the lying-in chamber with their hands foul with decomposing matters, and yet not communicate puerperal fever. But the round bacteria, unlike the rod-like variety under favorable conditions which we sum up under the term "predisposition of the patient," may penetrate the tissues, enter the lymphatics, and become distributed to the parenchymatous organs and to the serous cavities, and far away from the original site of infection may form sturdy colonies which excite destructive inflammation, or interfere with the performance of function. Or, again, the round bacteria may be disseminated through the system by portions of thrombi which form in veins as a consequence of inflammation, of pressure, or of enfeebled circulation. In all cases, it is true, the general infection may not take place. If the septic micrococci are of feeble vitality, or meet with active resistance from the invaded tissues, their progress may be arrested at a short distance from the point of entry, when they give rise to circumscribed inflammations, such as pelvic cellulitis and peritonitis.

Round bacteria thrive in putrid fluids, and are commonly present in them, but they may be absent, as we have seen, and they may be active for evil where putridity is absent. The odor of the discharges from a wound is not the sole criterion of their malignity.

With regard to prophylaxis, I think too great a burden could be thrown upon the practitioner by insisting upon non-essential details. My experience does not entitle me to expect great results from washing the floors, walls, and furniture with antiseptic solutions. At least in the lying-in hospitals, where I have witnessed many epidemics of puerperal fever, there has been a time when everything was vigorously scrubbed; no pictures adorned the walls, no carpets decked the floors, and carbolic acid was used without stint, but I have never observed that these precautions exerted the slightest influence in the prevention or the stamping out of puerperal fever. The fumes of sulphurous acid have since been substituted for the old-time scrubbings with the best results, and I would strenuously recommend the modes of disinfection employed by the Board of Health in all cases where there has been previously scarlatina, diphtheria, typhoid, or erysipelas in the household. In this connection I would state that a woman ought never to be confined in the

chamber adjacent to the bath-room, as I believe that puerperal women are extremely sensitive to sewer-gas poisons.

In normal confinements the uterus contracts down upon the child during its expulsion in such a way that no air naturally finds its way into the uterine cavity. There is no evidence that decomposition ever occurs normally in the uterine cavity. In the vagina, on the contrary, all the conditions favor putrefaction. There the lochia stagnate, and there are found heat, air, and moisture, the requisites of decomposition. Putrefaction of the uterine contents in such cases is not a primary, but a secondary condition, the decomposition beginning in the vagina creeping upward only after a distinct interval into the uterine cavity. This I consider an important fact, as in practice, where labor has been normal and there has been no needless interference with its progress, if the vagina is thoroughly cleansed it is rarely necessary to carry the injection into the uterine cavity.

In cases of difficult labor, on the contrary, where the hands or instruments have been introduced into the uterus, primary intra-uterine decomposition is rendered possible, and is then especially favored by the presence of bits of placenta or decidua. In such cases, where putrid intoxication alone exists, the intra-uterine douche is often the direct means of saving our patients' lives. It will, however, be far better if the disinfection is employed, not after the symptoms of poisoning have developed, but immediately after labor. The douche is then harmless, it stimulates the uterus to contract, and is a powerful means of preventing subsequent dangers. For my own part, I prefer the fountain to the siphon syringe, because with it there is less danger of introducing air, or of forcing a passage through the Fallopian tubes.

The douche, however, is not infallible. In cases where there has been inoculation of the round bacteria, they often invade the tissues beyond the original lesion, and it is of small avail to wash out the uterus when the victorious army has advanced far away from the point of attack. Washing the arm daily after vaccination does not prevent the development of vaccinia. Washing the uterus after the pelvic tissues are infiltrated with septic microspores may cut off the re-enforcements, but does not prevent the progress of puerperal septicæmia. I would advise, therefore, not to continue the uterine douche in cases where the results of the first thorough injection furnish the evidence of its impotence.

The results of antiseptics, as I understand them, have been most surprising in the great lying-in asylums of Europe. In Vienna in my student days the mortality often reached five per cent., whereas at present, in spite of the freedom with which the hospital is thrown open to students of every race, the deaths from septic causes are barely one in two hundred. In Prague, where Seyfert for many years fought the battle for the specific origin of puerperal fever, in Professor Streng's division, of eleven hundred confinements there has been no death from puerperal fever. But in these hospitals, and everywhere, the indiscriminate use of intra-uterine injections has been invariably followed by an increased mortality. With all the blessings from their employment, with the indubitable fact that they have been

the means of saving many lives, unless the indications for their use are carefully restricted, it is to be borne in mind that they are likewise capable of adding largely to the risks of the puerperal state, and of swelling the death-roll from puerperal causes.

MIRYACHIT,

A NEWLY DESCRIBED DISEASE OF THE NERVOUS SYSTEM,

AND ITS ANALOGUES.*

By WILLIAM A. HAMMOND, M. D.,

SURGEON-GENERAL, U. S. ARMY (RETIRED LIST); PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In a very interesting account of a journey from the Pacific Ocean through Asia to the United States, by Lieutenant B. H. Buckingham and Ensigns George C. Foulk and Walter McLean,† United States navy, I find an affection of the nervous system described which, on account of its remarkable characteristics, as well as by reason of certain known analogies, I think should be brought to the special notice of the medical profession. I quote from the work referred to the following account of this disease. The party is on the Ussuri River not far from its junction with the Amur in Eastern Siberia: "While we were walking on the bank here we observed our messmate, the captain of the general staff [of the Russian army], approach the steward of the boat suddenly, and, without any apparent reason or remark, clap his hands before his face; instantly the steward clapped his hands in the same manner, put on an angry look, and passed on. The incident was somewhat curious, as it involved a degree of familiarity with the steward hardly to have been expected. After this we observed a number of queer performances of the steward, and finally comprehended the situation. It seemed that he was afflicted with a peculiar mental or nervous disease, which forced him to imitate everything suddenly presented to his senses. Thus, when the captain slapped the paddle-box suddenly in the presence of the steward, the latter instantly gave it a similar thump; or if any noise were made suddenly, he seemed compelled against his will to imitate it instantly, and with remarkable accuracy. To annoy him, some of the passengers imitated pigs grunting, or called out absurd names; others clapped their hands and shouted, jumped, or threw their hats on the deck suddenly, and the poor steward, suddenly startled, would echo them all precisely, and sometimes several consecutively. Frequently he would expostulate, begging people not to startle him, and again would grow furiously angry, but even in the midst of his passion he would helplessly imitate some ridiculous shout or motion directed at him by his pitiless tormenters. Frequently he shut himself up in his pantry, which was without windows,

and locked the door, but even there he could be heard answering the grunts, shouts, or pounds on the bulkhead outside. He was a man of middle age, fair physique, rather intelligent in facial expression, and without the slightest indication in appearance of his disability. As we descended the bank to go on board the steamer some one gave a loud shout and threw his cap on the ground; looking about for the steward, for the shout was evidently made for his benefit, we saw him violently throw his cap, with a shout, into a chicken-coop, into which he was about to put the result of his foraging expedition, among the houses of the stanitzas.

"We afterward witnessed an incident which illustrated the extent of his disability. The captain of the steamer, running up to him, suddenly clapping his hands at the same time, accidentally slipped and fell hard on the deck; without having been touched by the captain, the steward instantly clapped his hands and shouted, and then, in powerless imitation, he too fell as hard and almost precisely in the same manner and position as the captain. In speaking of the steward's disorder, the captain of the general staff stated that it was not uncommon in Siberia; that he had seen a number of cases of it, and that it was commonest about Yakutsk, where the winter cold is extreme. Both sexes were subject to it, but men much less than women. It was known to Russians by the name of 'Miryachit.'"

So far as I am aware—and I have looked carefully through several books of travel in Siberia—no account of this curious disease has been hitherto published.

The description given by the naval officers at once, however, brings to mind the remarks made by the late Dr. George M. Beard, before the meeting of the American Neurological Association in 1880, relative to the "Jumpers" or "Jumping Frenchmen" of Maine and northern New Hampshire.*

In June, 1880, Dr. Beard visited Moosehead Lake, found the "Jumpers," and experimented with them. He ascertained that whatever order was given them was at once obeyed. Thus, one of the jumpers who was sitting in a chair with a knife in his hand was told to throw it, and he threw it quickly, so that it stuck in a beam opposite; at the same time he repeated the order to throw it with a cry of alarm not unlike that of hysteria or epilepsy. He also threw away his pipe, which he was filling with tobacco, when he was slapped upon the shoulder. Two jumpers standing near each other were told to strike, and they struck each other very forcibly. One jumper, when standing by a window, was suddenly commanded by a person on the other side of the window to jump, and he jumped up half a foot from the floor, repeating the order. When the commands are uttered in a quick, loud voice, the jumper repeats the order. When told to strike he strikes, when told to throw he throws whatever he may happen to have in his hand. Dr. Beard tried this power of repetition with the first part of the first line of Virgil's "Æneid" and the first part of the first line of Homer's "Iliad," and out-of-the-way words of the English language with which the jumper could not be familiar, and he repeated or echoed the sound of the word as

* "Journal of Nervous and Mental Diseases," vol. vii, 1880, p. 487.

* Read before the New York Neurological Society, February 5, 1884.

† "Observations upon the Korean Coast, Japanese-Korean Ports, and Siberia, made during a Journey from the Asiatic Station to the United States, through Siberia to Europe, June 3 to September 8, 1882." Published by the United States Navy Department, Washington, 1883, pp. 51.

it came to him in a quick, sharp voice, at the same time he jumped, or struck, or threw, or raised his shoulders, or made some other violent muscular motion. They could not help repeating the word or sound that came from the person that ordered them any more than they could help striking, dropping, throwing, jumping, or starting; all of these phenomena were indeed but parts of the general condition known as jumping. It was not necessary that the sound should come from a human being; any sudden or unexpected noise, as the explosion of a gun or pistol, the falling of a window, or the slamming of a door—provided it was unexpected and loud enough—would cause these jumpers to exhibit some one or all of these phenomena. One of these jumpers came very near cutting his throat while shaving, on hearing a door slam. They had been known to strike their fists against a red-hot stove, to jump into the fire and into water. They could not help striking their best friend if near them when ordered. The noise of a steam-whistle was especially obnoxious to them. One of these jumpers, when taking some bromide of sodium in a tumbler, was told to throw it, and he dashed the tumbler upon the floor. It was dangerous to startle them in any way when they had an axe or a knife in their hands. All of the jumpers agreed that it tired them to be jumped, and they dreaded it, but they were constantly annoyed by their companions.

From this description it will at once, I think, be perceived that there are striking analogies between "Miryachit" and this disorder of the "Jumping Frenchmen" of Maine. Indeed, it appears to me that, if the two affections were carefully studied, it would be found that they were identical, or that, at any rate, the phenomena of the one could readily be developed into those of the others. It is not stated that the subjects of "Miryachit" do what they are told to do. They require an example to reach their brains through the sense of sight or that of hearing, whereas the "Jumpers" do not apparently perform an act which is executed before them, but they require a command. It seems, however, that a "jumper" starts whenever any sudden noise reaches his ears.

In both classes of cases a suggestion of some kind is required, and then the act takes place independently of the will. There is another analogous condition known by the Germans as *Schlaftrunkenheit*, and to English and American neurologists as somnolentia, or sleep-drunkness. In this state an individual, on being suddenly awakened, commits some incongruous act of violence, oftentimes a murder. Sometimes this appears to be excited by a dream, but in others no such cause could be discovered.

Thus, a sentry fell asleep during his watch, and, being suddenly aroused by the officer in command, attacked the latter with his sword, and would have killed him but for the interposition of the bystanders. The result of the medical examination was that the act was involuntary, being the result of a violent confusion of mind consequent upon the sudden awaking from a profound sleep. Other cases are cited by Wharton and Stillé in their work on medical jurisprudence, by Hoffbauer, and by myself in "Sleep and its Derangements."

The following cases among others have occurred in my own experience:

A gentleman was roused one night by his wife, who heard the street-door bell ring. He got up, and, without paying attention to what she said, dragged the sheets off of the bed, tore them hurriedly into strips, and proceeded to tie the pieces together. She finally succeeded in bringing him to himself, when he said he had thought the house was on fire, and he was providing means for their escape. He did not recollect having had any dream of the kind, but was under the impression that the idea had occurred to him at the instant of his awaking.

Another was suddenly aroused from a sound sleep by the slamming of a window-shutter by the wind. He sprang instantly from his bed, and, seizing a chair that was near, hurled it with all his strength against the window. The noise of the breaking of glass fully awakened him. He explained that he imagined some one was trying to get into the room and had let his pistol fall on the floor, thereby producing the noise which had startled him.

In another case a man dreamed that he heard a voice telling him to jump out of the window. He at once arose, threw open the sash, and jumped to the ground below, fortunately only a distance of about ten feet, so that he was not injured beyond receiving a violent shock. Such a case as this appears to me to be very similar to those described by Dr. Beard in all its essential aspects.

A few years ago I had a gentleman under my charge who would attempt to execute any order given him while he was asleep by a person whispering into his ear. Thus, if told in this way to shout, he shouted as loud as he could; if ordered to get up, he at once jumped from the bed; if directed to repeat certain words, he said them, and so on.

I am not able to give any certain explanation of the phenomena of "Miryachit" or of the "Jumpers," or of certain of those cases of sleep-drunkness which seem to be of like character. But they all appear to be due to the fact that a motor impulse is excited by perceptions without the necessary concurrence of the volition of the individual to cause the discharge. They are, therefore, analogous to reflex actions, and especially to certain epileptic paroxysms due to reflex irritations. It would seem as though the nerve cells were very much in the condition of a package of dynamite or nitro-glycerin, in which a very slight impression is sufficient to effect a discharge of nerve force. They differ, however, from the epileptic paroxysm in the fact that the discharge is consonant with the perception—which is in these cases an irritation—and is hence an apparently logical act, whereas in epilepsy the discharge is more violent, is illogical, and does not cease with the cessation of the irritation.

Certainly the whole subject is of sufficient importance to demand the careful study of competent observers.

THE DANGER OF GLUTTONY.—The "Lancet" (January 5, 1884) reports two cases of death from gluttony. The first was that of a railway clerk, who went to bed apparently well on Christmas night, but died before morning. The stomach was found largely distended with undigested food, which had stopped the action of the heart. The other case was that of a negro, in whose stomach whole potatoes were found.

THE

NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*Published by
D. APPLETON & Co.Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEB. 16, 1884.

THE PROPOSED STATE FACULTY.

UNDER the title of "An Act to Establish the Medical Faculty of the University of the State of New York, to Regulate the Licensing of Practitioners of Physic and Surgery, and to further Regulate the Practice of Physic and Surgery," two bills were brought before the State society last week, as we have already apprised our readers. Both bills were reported by the Committee on Legislation, the one favorably, and the other unfavorably. For the sake of convenience, we shall term the bill favored by the committee the "committee's bill," and the other the "college bill," since it is understood to have emanated from some of the medical colleges.

As will have been gathered from the report of the meeting, given in our last issue, each bill had its supporters, but neither satisfied the meeting. Furthermore, so marked was the diversity of feeling that even a motion declaring it to be the sense of the meeting, in general terms, that a State licensing board was desirable, was passed only under cover of an amendment referring the whole matter to a new committee, so that it is not so plain as it might be that the meeting was really anything like unanimous in favoring legislation in the matter.

Such having been the temper of the meeting, it is manifest that no bill can meet with the cordial approval of the State society unless it differs radically from either of the two presented. To prepare a bill that will meet with such approval is the task the new committee has in hand, and that one of its members has guaranteed shall be accomplished. If the committee could ascertain the particular views held by men representing the various interests involved, including that of the community at large (an interest not to be lost sight of, as was clearly brought out in Dr. Jacobi's remarks), it would not only aid materially in shaping a bill that should meet the ends of justice, but it would go far to do away with the occasion for lengthy explanation and argument at the next meeting of the society. It is to be hoped, therefore—and, indeed, individual members of the committee have expressed themselves to that effect—that such representative men will lay their views before the profession. It seems better that they should give them public expression, in the columns of the medical journals, than lay them before the committee privately, for the former course will perhaps bring out discussion that otherwise might not be secured until the committee's action comes up before the society, at a time when there will be scant opportunity for a full interchange of opinions without neglect of the scientific work properly before the meeting. If such a discussion is entered upon, new arguments and new ways of looking at the matter will doubtless come to light, but this consideration by no means implies that the points

that were touched upon at Albany last week—those, namely, that were suggested by the two bills then brought forward—will not have to be dwelt upon still further. That our readers may consider these points in the light of the two bills, we shall try to give a brief statement of the points in which the bills differ from each other.

The committee's bill is in the main the same that was prepared by the Medical Society of the County of Erie, the full text of which we published several months since. The main points in which the college bill differs from it are the following: The college bill provides that no member of the faculty shall be or become connected with any medical school or college; the committee's bill provides only that the members of the faculty shall not be connected with a college or school that grants the degree of M. D.

The college bill leaves the constitution of the faculty wholly in the hands of the Governor; the committee's bill provides that "in the appointments made the representation of the several systems of medical practice recognized by the incorporated medical societies of this State shall be in the proportion of six, two, and one; that is to say, the system having the largest number of licensed practitioners to have six, that having the next largest to have two, and the remaining system to have one representative."

The committee's bill makes the license to practice obtainable only by passing an examination before this board; the college bill limits the necessity for this examination to those who are not "authorized by the diploma of some legally incorporated medical school or college in this State." The State faculty, however, is given authority to be present at the college examinations for the degree, to supervise and certify to the fact of those examinations (which shall be conducted in writing), and, in case of gross violation of proper methods of teaching, to recommend the Regents of the University to vacate, annul, or suspend the charter of the offending school. For unprofessional or dishonorable conduct, a license to practice may be revoked in like manner.

These points of difference between the two bills indicate the diversity of views entertained by two parties in the profession. It will be seen that they are radical, and that only a thoroughgoing renunciation of hobbies and a catholic devotion to the interests of medical education in the State will enable the new committee to bring about anything like a harmonious recommendation to the State society at its next annual meeting.

THE DISCUSSION ON PUERPERAL FEVER.

LAST week the discussion of Dr. Thomas's paper was concluded at the Academy of Medicine, and in this issue of the journal we are able to present the conclusion of Dr. Barker's paper, followed by the remarks of Dr. Lusk in the course of the discussion, and those made by Dr. Thomas in closing it; also, in a condensed form, those made by the other gentlemen who took part in the debate. From all these the reader may gather that the etiology and treatment of puerperal fever, especially in their relations to septicæmia, were thoroughly consid-

ered, and by men whose words are everywhere felt to express the highest state to which the obstetric art has reached in New York. It is to be regretted that discussions like this, enlisting men of such weight in the profession, can not oftener be arranged for the meetings of our larger societies, for they are of far greater profit to the mass of the profession than any number of off-hand discussions. Whoever will take the pains to read what was said on this occasion by the various speakers will, we think, get a much clearer idea of the real status of our knowledge of the subject, and of the disputed points connected with it, than if he were to study all the text-books on the Academy's shelves.

It is in human nature to cleave to the one side or the other in such a contest, but it is always well to inquire as to how much of the antagonism between the disputants' views is real and how much is only apparent. It is difficult to see what essential feature of Dr. Thomas's teachings there was that was radically contested, save the doctrine that puerperal fever is necessarily septæmia. Even on this point, too, the difference was perhaps practically rather one of definition than of real diversity of opinion as to substantial facts. It was well said by Dr. Lusk that one paper supplemented the other. The semblance of antagonism was enhanced, it must be confessed, by the warmth of the language employed by the two chief speakers, but, tempered as it was by the graceful terms of admiration and personal regard applied by each to the other, it should not be allowed to heighten the impression of disagreement upon the reader's mind. It seems to us, indeed, a matter for congratulation that a discussion should have been carried on with so much vehemence, involving even an appeal to the dangerous weapon, ridicule, without the slightest approach to unkind feeling; it shows the depth of the men's convictions, and it shows how the emotions may be kept down while the intellect is at its greatest strain. We are much mistaken if just such tilts do not strengthen rather than weaken our *esprit de corps*.

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 12, 1884:

DISEASES.	Week ending Feb. 5.		Week ending Feb. 12.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	1	0	1	0
Typhoid Fever.....	10	4	8	4
Scarlet Fever.....	94	12	91	15
Cerebro-spinal meningitis.....	6	6	13	9
Measles.....	39	4	62	11
Diphtheria.....	27	10	47	19

THE STATE LUNATIC ASYLUM AT UTICA.—Proceedings have been begun in the Legislature looking to an investigation of the management of the institution, the immediate occasion being a recent fatal assault upon an inmate. Some of the legislators seem a good deal excited over the matter, one gentleman having even proposed that the superintendent be suspended pending the investigation.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.—The president of the faculty informs us that we were in error in stat-

ing, as we did last week, that Dr. Spitzka had resigned, although our authority for the statement was a member of the faculty. The secretary now asks us to state that the following-named gentlemen have been appointed professors: Dr. W. O. Moore, ophthalmology and otology; Dr. W. F. Flubrer, clinical surgery; and Dr. Bache McE. Emmet, gynecology.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 2, 1884, to February 9, 1884:*

BARNETT, RICHARDS, Captain and Assistant Surgeon. Granted leave of absence for six months on account of disability. Par. 8, S. O. 13, A. G. O., January 16, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending February 9, 1884:*

VAN REYKEN, W. K., Surgeon, from the U. S. S. Powhatan to the Navy Department, as Assistant to the Bureau of Medicine and Surgery, and Acting Chief of that Bureau.

HOEHLING, A. A., Surgeon, from special duty at Washington to the Powhatan.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, February 18th:* Medico-Chirurgical Society of German Physicians.

Tuesday, February 19th: New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Roman Medical Society (private); Medical Societies of the Counties of Kings and Westchester, N. Y.; Ogdensburg, N. Y., Medical Association.

Wednesday, February 20th: New Jersey Academy of Medicine (Newark).

Thursday, February 21st: New York Academy of Medicine. (1. The Differences in Form of the Adult Head, by Dr. J. C. Dalton. 2. An Improved Method in the Treatment of Certain Forms of Skin Disease, by Dr. P. Albert Morrow.)

Friday, February 22d: New York Clinical Society (private); New York Society of German Physicians (private); Yorkville Medical Association (private).

Saturday, February 23d: New York Medical and Surgical Society (private).

Letters to the Editor.

CARBOLIC-ACID VAGINAL INJECTIONS AND RETAINED PLACENTA.

LUMBERTOFT, WEST VIRGINIA, January 25, 1884.

To the Editor of the New York Medical Journal:

SIR: Since reading Dr. Thomas's paper on "The Prevention and Treatment of Puerperal Fever" (read before the New York Academy of Medicine, December 6, 1883), I have used the antiseptic precautions as prescribed therein in three cases of labor, with excellent results as regards puerperal fever; but what I would inquire into is the fact that in two of the three cases I met with spasmodic contractions of the os uteri and temporary retention of the placenta. The contractions were not very obstinate, and caused but little difficulty and some delay. This condition has not frequently occurred in my practice, and I therefore attributed it to the use of the carbolic-acid solution. Do you know of a similar experience?

Yours truly,

A. LAUTZ HUPP, M. D.

TINCTURE OF IODINE IN PAPULAR ECZEMA.

INDIANAPOLIS, February 4, 1884.

To the Editor of the New York Medical Journal:

SIR: Physicians occasionally have excessive annoyance from intractable cases of lichen agrius. In a recent case, started by two doses of morphine acting on an idiosyncrasy, where all soothing ointments, lotions, and internal treatment failed, I painted the aggregations of papules with Churchill's tincture of iodine, putting on three coats, well dried in each time. Two would probably have done, for it blistered the whole surface. But in five days the cuticle peeled, the skin was left sound, and all the outlying untouched eruption had entirely disappeared. The cure was complete. Hoping the suggestion may be so made public as to help some other worried physician,

I am yours,

L. D. WATERMAN, M. D.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of February 7, 1884.

THE PRESIDENT, FORDYCE BARKER, M. D., LL. D., in the chair.

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.—

The adjourned discussion on Dr. T. Gaillard Thomas's paper on this subject, published in our issue of December 15, 1883, was opened with a paper by the president, which will be found on page 151.

Dr. W. M. CHAMBERLAIN did not propose to enter into the general discussion of this subject, or of either of the papers which had been read, but would like to notice some remarks made at the first discussion upon the glass tube, mentioned by Dr. Thomas, and devised some years since by himself for washing out the septic puerperal uterus. Dr. Thomas had stated that he had found occasion to make some modifications in the instrument, namely, to bring the openings nearer together at the uterine end, and to make an opening at the extreme end. The first of these Dr. Chamberlain had long since done, but about the propriety of the second he had still some doubt. Another gentleman had criticised the tube as too large, and this suggested a point of much diagnostic value, as it seemed to him, in determining in what cases intra-uterine injections should be employed, and when they should be omitted, or, if employed, suspended.

In every autopsy of a woman dead of puerperal fever which Dr. Chamberlain had seen, he had found the uterus large, soft, and flaccid, and in every case seen during life, since he became critical on this point, the same condition had existed.

There were different grades of septicæmia. For instance, there were those that followed after slight breaks in the mucous membranes of the genital passages, a little tear of the cervix, vagina, or perineum; marked by a gradual rise of temperature, day by day, until, a week or more after delivery, the patient might pass into a critical condition. This was the analogue of surgical fever, and was to be distinguished from the explosive form, which was generally seen within forty-eight or seventy-two hours after delivery, ushered in by a sharp chill, lochial fetor, rapid rise of temperature, restlessness, anxiety, and prostration.

When this existed, so far as he knew, it always suspended the process of involution; the uterus became relaxed, the dis-

charges accumulated in it and were partially retained, and the womb became a hot-bed where microbes fructified in profusion, or the virus of putridity fermented unrestrained.

These were the cases, he believed, which required antiseptic irrigation, and in these the os was so patulous and so soft that a large tube would pass readily, and would give a leverage to lift the soft anterior lip, leaving beneath it a space for the exit of the injected fluid. In such cases and in such tissues a large bearing surface was safer, even as a large sound was safer than a small one in a soft urethra, while, if the uterus was itself thus open, there was reason to believe that its tubes and sinuses might also be patulous and so liable to be entered or injected by a small tube, particularly if it were open at the end.

The remarkable studies of Dr. Garrigues had shown us that the ordinary lochial discharge in a normal delivery was not noxious if access of a ferment or a contagium from without were carefully excluded.

To Dr. Hunter's objection—that in his (Dr. Chamberlain's) tube, as first made, the antiseptic fluid escaped into the vagina before reaching the uterus—he could only say that one very narrow hole could not empty a large tube rapidly, and that, clinically, he had had the best results from its use.

He would repeat that he found no occasion for irrigating a uterus in which involution was going on at or about the normal rate, for such a uterus did not contain the septic material to be washed away. In some, at least, of the cases in which the injections had seemed to do harm, it was to be ascribed to the failure to make this distinction.

Dr. H. T. HANKS read a statement of his views, in substantial agreement with those expressed by Dr. Thomas, with the exception that in many cases he thought it unnecessary to resort to all the details of the antiseptic treatment. For example, he would not use ante-partum vaginal injections, nor would he apply the carbolyzed napkin. After labor, however, he always used vaginal injections, and believed them to be necessary.

Dr. WILLIAM T. LUSK was the next speaker. [Dr. Lusk's remarks will be found on page 189.]

Dr. PAUL F. MUNDÉ had listened with much pleasure and interest to Dr. Thomas's paper and to the discussion, but he had felt at a loss as to what to say himself. Since he began the practice of obstetrics, about eighteen years ago, he had seen a number of cases of puerperal fever in hospital and private practice, and it had become his custom to treat the disease locally—just as a wound which gave rise to septic infection would be treated in any other part of the body—and he had to confess his conviction that puerperal fever was, properly speaking, puerperal septicæmia; yet he would qualify this statement somewhat. Certainly, when he was called to a case in which he found an offensive discharge from the uterine cavity, with rise of temperature, preceded or not by a chill, he felt it his duty to wash out the cavity of the uterus, and, if he failed to do this, he felt that he had failed in his duty to himself and to his patient. But he had seen cases in which, in the entire absence of evidence of infection of the uterus or of the parametrium, he could not help feeling that the condition was something different from what we found in cases of septic infection, and that there were instances where we could not exactly trace the source of the trouble to septic infection. In short, he was obliged to subscribe to the views of the honored president in so far as to believe that there were some forms of puerperal fever which we could not call puerperal septicæmia. What the nature of the poison was in these exceptional forms of puerperal fever he could not say. He saw no reason why there might not be two forms of fever in the puerperal woman: one being what was known as puerperal septicæmia, and the other a zymotic, infectious disease—puerperal fever proper. At any rate, when-

ever he had a case of fever during the puerperal state, with offensive lochia, he took the risk of washing out the uterus, and, even if it were not necessary, he felt that, if properly done, it would probably do no harm.

With regard to prophylactic vaginal injections, much had been said for and against them. He himself had employed them regularly, but he must admit that the objections that had been brought forward against them might have some foundation. Probably one of the chief reasons why he used them was that the nurse and the patient commonly thought that all had not been done that should have been done if they were neglected, and would surely impute anything that might happen to their omission. He objected to the use of the Davidson syringe for either vaginal or uterine injections; cases had been reported in which liquid or air had been forced by it into the uterine sinuses, resulting in death, and he had seen one case of dangerous shock from an involuntary injection of the uterus by the nurse on the ninth day, while giving a vaginal injection with this syringe. He always used a fountain syringe, as Dr. Thomas had recommended in his paper, and he thought its advantages should be still more emphasized. The mere absence of discharge from the uterus did not contraindicate the injections; indeed, it might be a special reason for employing them. This was illustrated in a case in which the discharge had ceased simply because the uterus had become anteverted, and the uterine cavity closed in consequence. A chill took place, and the temperature rose to 105° F., but these symptoms were relieved at once by straightening the uterus by bimanual manipulation and washing out its cavity. He doubted the advantage of a terminal opening in the Chamberlain tube. He agreed with Dr. Lusk that, when the temperature remained high in spite of the injections, the "victorious army" had probably gone on into the general system, and our washings simply brought away the rear guard, and were liable to do more harm than good if continued.

Dr. THOMAS then closed the discussion with the remarks which will be found on page 186.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of November 14, 1883.

THE BACILLUS TUBERCULOSIS AND THE ETIOLOGY OF TUBERCULOSIS. IS CONSUMPTION CONTAGIOUS?—Dr. H. F. FORMAD read a second communication with this title, as follows:

General Consideration.—A little over a year ago* I had the honor of presenting for your consideration some anatomical points in refutation of the etiological relations of the *Bacillus tuberculosis*. At that time I announced some original observations regarding the histology of scrofulous tissue, tending to place the question of heredity in tuberculous disease upon an anatomical basis. These peculiarities of scrofulous tissues I submitted as elucidating the etiology of tuberculosis, showing that the peculiar histological condition of the individual, under the influence of simple irritants, and not the character of the irritant, is responsible for tubercular inflammation. It gives me pleasure to state that these observations have since been confirmed by several competent histologists, whose articles on this subject will soon appear in print; besides which, a general interest has been manifested by favorable comments both in America and abroad. Shortly before the publication of these observations, Koch, of Berlin, had brought forward the discovery of

the now famous bacillus tuberculosis, affirming it to be the sole cause of pulmonary phthisis and other forms of tubercular disease, and claiming for it, besides exclusive pathogenetic properties, special morphological and chemical characteristics. In my first paper I denied some of these propositions upon grounds of personal investigation, and subsequently Koch's researches were also severely criticised by a number of other observers.

As interesting and valuable as the discovery of Koch is, from a biological standpoint, its practical value is, in my opinion, decidedly over-estimated, and has not nearly the significance for medical science which the enthusiastic followers of Koch ascribe to it. The influence of the discovery was, however, great in strengthening the traditional and unwarranted belief in the contagiousness of phthisis, as held by a small part of the profession and community. On the other hand, this belief led to the popularity of the discovery. In this respect the bacillus theory has perhaps been harmful, and, taking the consequences into consideration, we should not accept such a theory without the closest scrutiny.

Two practical benefits may accrue from this discovery. The first is that the fear of the effects of the bacillus may induce greater cleanliness in hospital management and enforce improvement in hygienic matters in general. It is doubtful whether the removal and prompt destruction of the sputum would have any influence in checking the spread of phthisis, as the disease is found as often, if not oftener, in the clean palaces of the wealthy as in the unclean huts of the poor. The second benefit resulting from the bacillus theory may be that physicians may become induced to make more use of the microscope in diagnosis; yet, in this respect, the general use of the microscope is hardly practicable on account of the thorough technical experience required.

To-day, while the bacillus is acknowledged as a common morphological concomitant of tubercle, pathogenetic properties are denied it by the best pathologists and clinicians, on account of a want of sufficient confirmation of the evidence thus far offered.

The followers of Koch's theory are, however, numerous, but they are recruited largely from the ranks of clinical teachers, book-writers, and others possessing no opportunities for personal investigation.

It may be well to state that, upon my visit to Koch last summer, made with the purpose of doing justice to this important question, I was gratified in many respects. I found Koch an earnest and conscientious worker, and not so dogmatic and extreme in his views as would appear from his writings; nor is he so self-satisfied and so rash to jump at conclusions as some of his followers are. Koch has the co-operation of an excellent staff of assistants, all able mycologists; but it was a matter of surprise to me that there was not a single competent pathologist connected with Koch's laboratory; and such services are evidently much needed to give to the observations made there the proper interpretation from a biological and anatomical standpoint. I was also pleased to learn in Berlin that the discovery of the bacillus was exaggerated, not so much by Koch himself as by the Imperial Board of Health, which employs him, and by his over-zealous followers in the profession. There is strong evidence, however, that Koch's investigations are biased by the determination to find for each specific disease a specific fungus.

Following out the various phases in the study of tuberculosis, I am sorry to see that the entire subject is now being considered from a purely etiological basis with reference to bacteria, while the study of the anatomical and biological relations is wholly neglected.

I admire the beautiful bacteridian discoveries of Klebs, and particularly those of Koch, in connection with the etiology of

* "Studies from the Pathological Laboratory of the University of Pennsylvania," xi; "The Bacillus Tuberculosis and some Anatomical Points which suggest the Refutation of its Etiological Relation with Tuberculosis," by H. F. Formad. Read before this society, October 18, 1882.

tuberculosis. The accomplishment of these results is a triumph for psychology and scientific botany; but these studies are much too one-sided to have an application to scientific medicine. The bacillus is there! It is concomitant with most tubercular lesions. It is diagnostic of tuberculous change. It is, on account of its irritant properties, one of the causes of tuberculosis. But this forms no reason for asserting that tuberculosis should be considered a contagious disease, without further investigation and proof. A contagious disease can have only one cause. I can not agree with those who define the predisposition to phthisis as being a condition of the organism which offers a favorable soil for the tubercle bacillus. Nor can I believe that inheritance is explained by subsequent infection from cohabitation; e. g., that children become scrofulous by living with consumptive parents.

The latest fruits of the bacillus studies have even inspired Baumgarten (*"Centralblatt. f. d. med. Wissensch."*, Aug. 4, 1883) and several others to come to the conclusion, in reference to the hereditary nature of tuberculosis, that the bacillus is transmitted in its larval state from mother to fetus in intra-uterine life! One would think, however, that one of the most wonderful effects of the tubercle bacillus was manifested by the change it produced in the direction of the reasoning of some of our pathological and clinical investigators both at home and abroad.

Some of the younger pathologists are affected by a regular fanaticism for bacterian studies in tuberculosis. These studies now take the place of their former excellent pathologico-anatomical studies. Consideration is no longer given to the tissue changes, or the nidus, which invites the bacteria and nourishes them. In fact, Koch's followers, in their enthusiasm, exaggerate matters, and to Koch's own amusement, go farther in their bacillus speculations than he himself thinks justifiable. It is really painful to read how some of the younger German pathologists, and a few of the prominent English surgeons, under the influence of the bacillus craze, will make, in their publications, assertions entirely unwarrantable. They describe, for instance, with the greatest ingenuity and exquisite minuteness, how "one or more bacilli" will produce certain histological changes in the lungs or in the peritonæum, designating the exact route to the same; how the different cells, the lymphatics, and the blood-vessels are affected; how the bacilli convert one variety of cells into another; how they manufacture giant cells and cheesy material; how acute and chronic phthisis are produced by the bacilli, and the quantity necessary for each; how tubercles develop only and exactly in those places where the bacillus becomes lodged; how, if bacilli alone are inhaled, miliary tubercles form, and how, if the bacillus is accompanied by some other irritants, a broncho-pneumonia will ensue.

All these statements are made by scientific medical men and pathologists, and offered as broad facts, in full earnest! I only have to say that here evidently observation is replaced by imagination and speculation; and all this is done for the sake of the convenience in explaining a disease by pretty hypotheses.

The only men who attempted to repeat Koch's experiments, besides the work done in the pathological laboratory of the University of Pennsylvania, were Spina (*"Studien über Tuberculose,"* Wien, 1883) and Watson Cheyne. Of the latter two scientists, Spina came to results entirely different from those of Koch, and they disprove beyond doubt some parts of Koch's hypothesis. From an analytical and critical point of view, Spina's studies of tuberculosis are excellent, but the technical part of his investigation is deficient, and hence not satisfactory. Watson Cheyne, to whom the British Association for Advancement of Science by Research had intrusted the investigation of tuberculosis, and the testing of Koch's researches, did not do

justice to his mission. From Cheyne's report (*"The Practitioner,"* April, 1883) it is seen that he made no earnest attempt to study the nature of tuberculosis, because all he did was to study and experiment with bacteria met with in tuberculous lesions. He went to see some of the different mycologists, consulting only believers in the germ theory; obtained some French and German bacteridial material, and, after testing the same, he reports with great emphasis that Koch's bacilli are a more genuine tubercular virus than Klebs's or Toussaint's micrococci. He did not inquire, nor did he care, whether tuberculosis might have any other cause! He simply imitated some of Koch's experiments with the bacillus material on rabbits and guinea-pigs (only), and obtained, of course, the same results. Furthermore, he made some control experiments, which, as I will show, pass for naught, as they are much more deficient than those of Koch.

There are a number of excellent studies in reference to the occurrence of bacilli in the sputum and in tuberculous tissues; but the main part of Koch's hypothesis—I, e., the etiological relation of these bacilli to tubercular disease—remains still unconfirmed.

My own researches on tuberculosis were made from a standpoint different from that of Koch, and they were undertaken five years ago, being carried on continuously since that time by myself and assistants. My object was to investigate scientifically the natural history of the disease, without being influenced by any preconceived views. While due attention was paid to external agencies in the production of tuberculosis, the part played by the animal or human organism itself, the behavior of its component cells, and the primary changes in the tissues, were not lost sight of. I may state that I was fortunate enough to be able to utilize the material of over four hundred cases of tubercular disease from the autopsy-table, including a number of cases studied in the pathological institutes in Europe at various times.

My present research on tuberculosis with special reference to the bacillus question was carried on during the last year and a half under the auspices of the Provost of the University of Pennsylvania, Dr. William Pepper. This communication should not be considered a report on my investigations, as these are not yet concluded; but a detailed report of these investigations will be made next summer. Some of the positive results achieved will, however, be referred to in the present paper; otherwise it merely embodies a general critical survey of the question of the etiology of tuberculosis, based upon a careful perusal of the literature of the subject and upon personal observation.

I may state at the outset that, while the results of my observations force me to-day to make some concessions to Koch, namely, that his bacillus, on account of its irritative properties, can produce tuberculosis under certain conditions, I am firmer than ever in my former conclusions, from the results of repeated observations, that tuberculosis may arise from other causes. The bacillus may be one of the causes, conditionally, but it is not the cause. The question of predisposition stands in the way of the acceptance of the bacillus theory. Furthermore, I will try to show that tuberculosis is not a contagious disease, and it is particularly in reference to this that I am glad to bring the present subject before the society, desiring to profit by the discussion which is to follow as a result of the experience and the clinical observation of the individual members of the society.

The question of the contagiousness of phthisis is one of supreme importance, not only from its scientific, but also from its social aspects.

For convenience in treating the subject of the etiology of tuberculosis, I shall speak of it under the following headings:

1. The definition, the anatomical character, and the etiology of tubercular lesions, including pulmonary phthisis.
2. The predisposition; the predisposing conditions; scrofulosis.
3. Tuberculosis without predisposition, due to inflammation of serous membranes.
4. Question of contagiousness; clinical aspect.
5. The bacillus tuberculosis.
6. Experiments—*pro* and *contra*; traumatic tuberculosis.

Conclusions.

All these considerations will have to be, of necessity, very brief.

The Definition, the Anatomical Character, and the Etiology of Tubercular Lesions, including Pulmonary Phthisis.—No definite understanding concerning a disease can be arrived at unless some fixed conception of the anatomical characters and various expressions of the lesions of that disease is formed. Thus, as regards the question of tuberculosis and pulmonary phthisis, the matter would be much simpler if a general understanding could be arrived at as to the definition of tuberculosis and phthisis in their different anatomical manifestations. The pivot of the question is, what to call a tubercle, or a tubercular lesion.

The traditional conception of a tubercle being a miliary node, the belief is that nothing is tuberculosis unless expressed by nodes, and that everything is tuberculosis that appears to the eye as containing nodes. These misconceptions are what bring the confusion and prevent the settlement of the question of tuberculosis, both at the post-mortem table and in the hands of the experimenter. One of the results of this confusion is that some clinicians divide pulmonary phthisis into catarrhal, cheesy, fibroid, and tubercular proper, because they do not see tubercle nodules in some of these forms of phthisis. They seem not to be aware of the fact that miliary tubercles do not belong necessarily to the picture of pulmonary phthisis; and, on the other hand, that those nodes which occasionally appear as miliary tubercles are not miliary tubercles at all, but are only miliary foci of broncho-pneumonia, due to aspiration, as will be explained later. Miliary tubercles, if at all present, usually form a part of a general disease—a tuberculosis of the whole body. In rare instances, when the miliary eruption takes its departure from the lung, the miliary nodules may be limited to the lung.

A more serious matter is the mistake that experimenters make of interpreting as tubercles the so-called inhalation tuberculosis, artificially produced in animals by means of a spray with tuberculous and other matter. The nodules produced in the lung under these circumstances are not miliary tubercles—in fact, no tubercles at all. They are simply miliary broncho-pneumonic foci, limited to those terminal collections of air-vesicles called acini, in which some of the inhaled irritative material becomes lodged. The natural round boundaries of these acini correspond exactly to the usual size of miliary tubercles, and appear as such even under the microscope, although filled merely with an unorganized inflammatory exudate. The uniform distribution of these foci is due to the fact that the inhaled irritating particles are distributed only to individual, and the most accessible, bronchioles and acini, thus simulating a true miliary tuberculosis of the lung. Similar broncho-pneumonic foci occur in the human lung from self-aspiration of tuberculous material from a primary focus to some other portion of the lung or throughout the whole lung. This was proved long ago, but the inhalation experimenters appear not to be aware of that fact. Careful personal observations and experiments, to be recorded in my forthcoming report, have convinced me that such inhalation experiments prove nothing, either for or against the contagiousness of tuberculosis, in connection with which they have been brought

forward as the strongest affirmative proofs. Furthermore, it must also be remembered that the so-called experimental inhalation tubercles, as a rule, remain local.

On the other hand, miliary nodes or tubercles are met with, not only in tubercular lesions, but also in a variety of similar and dissimilar lesions, such as pearl disease, or bovine tuberculosis, lupus, leprosy, glanders, actinomycosis, chancre and gummata, cancer, typhoid infiltration, lymphomatous and leukæmic lesions. All these lesions, even cancer ("miliary carcinoma"), are able to give rise to exquisite miliary disseminations or eruptions, although these are most frequently observed in tuberculosis. We already recognize leprous, lupous, glanderous, syphilitic, and other tubercles, in contradistinction to tuberculous or scrofulous tubercles.

To these nodular formations may be added a variety of minute inflammatory foci of granulation tissue, organized around minute foreign bodies introduced experimentally into various tissues; also, "false tubercles," such as mere unorganized collections of lymphoid cells, held together by some fibrin or by some artificial or natural round boundaries, such as is the case with the "inhalation tubercles" referred to; and further, also, the eruption and follicular enlargements in the skin and mucous membranes.

The question now arises, how to distinguish between these various kinds of nodules, apart from their clinical features. They may all undergo a cheesy or a fibrous change, may calcify, and may contain giant cells. In all, bacilli may be found if a cheesy change occurs, or tends to occur, save in cancer and in leukæmic formation. Without desiring to appear skeptical, I must say, however, that it takes the skill of a Koch to differentiate sometimes the bacilli met with in the various kinds of nodes, even after applying all micro-chemical tests.

The true tuberculous tubercles occasionally do not show any bacilli whatever, as I will prove from personal observation and from the reliable testimony of others. It will also be shown that the only test now left for determining the pathogenic peculiarity of tubercle—namely, the asserted exclusive property to produce tuberculosis—is conditional and uncertain, since substances not tuberculous may, under similar conditions, have the same effect. Therefore it is impossible to define tuberculosis, either by its anatomical peculiarity or by the pathogenic property of its nodes.

Another important point in the natural history of tuberculosis is the cheesy degeneration of its products; but here again we are surrounded by difficulty if we take only the cheesy product into consideration, because all the lesions mentioned before as being characterized by, and as being capable of, nodular eruptions, have the tendency to undergo cheesy change. Besides this, simple inflammatory products have been observed to undergo a similar change, as is exemplified by that form of cheesy hepatization sometimes following croupous pneumonia, and also by certain forms of rapid necrotic changes, such as occur in acute septic inflammations, designated lately by the name of coagulation necrosis. It must, however, be remembered that the total absence of cheesy masses in the bodies of tuberculous subjects has been observed. To tell tuberculosis from allied lesions is only possible after a consideration of the soil in which it develops, and the location of the products, together with the clinical and anatomical manifestations.

What is the origin of tubercle nodules? The primary occurrence of miliary tubercle nodes is, to my mind, very questionable. I have never seen them occur without the co-existence of diffuse granulation tubercle. This granulation tubercle is recognized by all as being a simple inflammatory granulation tissue, characterized by cells somewhat larger than ordinary lymphoid cells, containing usually giant cells, but undergoing

very readily cheesy change on account of its deficiency in blood-vessels. This tissue is regarded by most pathologists as secondary to milary tubercles; but I think, after careful observation, that the reverse is the case; because I have never seen upon the post-mortem table, or in animals, *primary* milary nodes without the granulation tissue, while the granulation-tubercle tissue does exist very frequently without the nodes. Moreover, *primary milary tuberculosis* is unknown.

That tubercle is primarily a simple granulation tissue of inflammatory origin has been proved experimentally. E. Ziegler ("Centr. bl. f. d. med. Wissensch.," 1874, No. II) made the following interesting experiment: He inserted below the skin or into the peritonæum of animals a number of pairs of glass covers, each pair glued together in such a manner that between them there existed an interspace just large enough to allow the entrance of white blood corpuscles; and these corpuscles, not being severed from the body of the animal, then formed a tissue between these plates of glass, which, upon removal after various periods, could be readily examined under the microscope, and the conditions of tissue formation traced. Under these circumstances it was observed that, whenever blood-vessels had developed in the new-formed tissue between the glass plates, an organization of the cells into a perfect connective tissue took place; but, when the formation of blood-vessels had failed to occur, a tissue simulating tubercle tissue was formed, made up of epithelioid and giant cells, and cheesy changes had occurred. Ziegler very properly declared the latter product to be tubercle tissue. I have had, and have at present, ample opportunity to corroborate the accuracy of these observations. Ziegler's experiments were repeated in the pathological laboratory of the University of Pennsylvania by Hammer, and at present are being carried on by Woodnut. By these experiments, made, with slight modification, after the method of Ziegler, under varying conditions and upon various animals, it was shown that the granulation tissue gradually gave origin to tubercle nodules. Furthermore, these experiments showed that the tubercle nodes and cheesy changes ensued without the action of bacilli, as the latter were found not to be present when proper care was taken, during the execution of the experiment, to exclude them.

From the examination of tubercular tissue from various sources, I may say that I have seldom succeeded in finding tubercle bacilli in newly formed tubercular tissue made up of small lymphoid cells. In older tubercular tissue, made up of opaque epithelioid cells and giant cells with a nodular arrangement, particularly when this tissue is undergoing necrotic change, bacilli are quite common, except in some forms of tubercles of serous membranes, to be referred to later. Tubercle tissue that has undergone a complete cheesy change contains the greatest number of bacilli. Cheesy matter of any source is a dead substance, and it is usually inhabited by bacilli, if these get access to it, while other bacteria are scarce on this nidus.

Examination of materials from the autopsy-table shows that tubercle expresses itself in various manners. Primarily, tubercle occurs as a mere infiltration of lymphoid cells in the adventitia of blood-vessels, or as small nodular masses of lymphoid infiltration around blood-vessels or ducts of any kind; or tubercle tissue may organize within blood-vessels and various ducts. Sometimes tubercle appears as a diffuse lymphoid infiltration, extending over a larger area, showing a greater or less tendency toward the formation of nodes and cheesy or fibroid change, as in the lungs. Tubercle tissue may form masses of the size of a hen's egg, particularly in the brain and serous membranes. In the lungs, in racemose glands, and in mucous membranes, catarrhal changes always follow the tubercle infiltration. On serous surfaces primary tubercles appear often as flat or nodulated patches of various sizes (in the peritonæum), or as fungoid vege-

tations (in synovial cavities), or even as large plastic masses (in the omentum). In the skin and mucous membranes, tubercles produce eruptions, ulcers, or nodular indurations; in bones, caries, with abscess formation in surrounding parts (cold abscesses). Fibroid capsules, made up of connective tissue, due to reactive inflammation, inclose often smaller or larger tubercular masses, especially if these have undergone cheesy change.

Primary tubercle manifests itself quite variously in different animals. In guinea-pigs and rabbits it appears mainly as small cellular infiltrates; in dogs it often undergoes a fibroid change; in goats, and especially in cattle, tubercle often forms large nodular, sometimes pedunculated, masses which often calcify; * in birds it forms, preferably in the liver, large, round mulberry masses, which, on section, appear sometimes as horny radiating structures.

Secondary tubercle presents an aspect entirely different from primary tubercle, and it manifests itself in nearly all instances in but one form, namely, as a fine milary eruption representing those well-known gray, semi-transparent nodules, of the size of a millet-seed, called milary tubercles. These seem to lie in the perivascular lymph-spaces, and are probably distributed throughout the body mainly by means of these lymph-channels of the blood-vessel walls. Tubercles do not occur in avascular tissues. There is, however, a second form of embolic or metastatic tuberculosis, which evidently distributes itself by the blood-current proper, and it appears in the form of conical masses or round nodes, which may reach the size of a walnut and are located usually at the bifurcation of arteries. No mention of this form of tubercle is made in text-books, although upon the post-mortem table it is a very common occurrence. Especially is it seen in the lung and, more rarely, in the spleen and liver.

Taking into consideration the enormous frequency of local tubercular lesions (counting pulmonary phthisis in this category), the occurrence of secondary or true milary tuberculosis must be considered rare. A tuberculosis affecting the lining of even the whole peritoneal cavity, including its lymphatic glands, or that of the pleural sacs, or that involving one or both lungs, must, when occurring thus in but one locality, be considered a local tuberculosis. In such instances the tubercle spreads by continuity of structure.

It is a fact, established by Virchow, that tuberculosis is at first a local disease, and only becomes generalized secondarily. This generalization does not affect the blood, as in infectious diseases, but it takes place simply as an embolic process, as in some tumors. Local tuberculosis in external organs and accessible lymph-glands is often a harmless affection. It is strongly related to primary tumors. Complete early removal of local tubercular lesions is practiced successfully in Europe. Volkmann and others have removed, for instance, lymphatic glands, testes, and joints affected with fungoid synovitis, with the object of preventing secondary tuberculosis, and have thus prevented a general milary tuberculosis.

Nor should a gloomy prognosis be given in early phthisis. It is astonishing what a large number of healed cavities and cicatrices in the apices of lungs are found on the post-mortem table, indicating the healing of phthisis in persons who long subsequently died from some other causes in later life.

We have seen that tuberculosis manifests itself quite differently as to structure, appearance, distribution, and termination, in the various animals, and even differently in the various organs

* I have met with, on the autopsy-table of the Philadelphia Hospital, two cases of tuberculosis in man that were identical in every respect with bovine tuberculosis. Dr. Creighton, of Cambridge, England, describes a number of cases from his own observation and collected from literature. "Bovine Tuberculosis," London, 1881.

of one individual. Our studies have shown that these variations in the expression of tuberculosis depend upon the structural peculiarities of the various kinds of animals, and sometimes even upon the difference of the structure in animals of the same species. We have also seen that even in human beings tubercle tissue may manifest itself in various forms. In some individuals it develops rapidly, and spreads over large areas, becoming generalized and undergoing speedy cheesy change; in other individuals it develops slowly, fibroid change predominating; and in others the tuberculous product may calcify. In most individuals tubercular lesions may remain entirely local.

It is well known from clinical experience that the general condition of the organism has very much to do with the healing of a local tuberculosis. A local tuberculous inflammation may heal or become arrested in its progress if the patient "gets strong," or it becomes more developed and aggravated if his general health "runs down." Observation has further shown that any simple non-specific wound in a weak, ill-nourished individual may fail to heal, becoming unamenable to treatment, and probably assuming a tubercular character.

In some animals spontaneous tuberculosis is unknown, and, while some animals are easily tuberculizable experimentally, in others tuberculosis can not be produced.

It is in accordance with experience that in a large number of families the predisposition to tuberculosis is hereditary, and that their members die promptly of phthisis at a certain age from the effects of a simple "cold," while in the history of other families this affection is unknown. Every individual is liable to acquire syphilis, small-pox, and other contagious diseases, but it is proved that not every one can have tuberculosis. A special predisposition and a special individual are required. In such an individual, a simple inflammation, resulting from any cause whatever, can produce tuberculosis.

Therefore, for the development of tuberculosis, two conditions are necessary: 1. A *definite* soil. 2. An *indefinite* irritant. The reaction of the soil is always the same under the influence of any irritant, whether that irritant be a bacillus or not, since the result (tuberculosis) following a lesion in such a soil depends upon the character of the soil and not upon the character of the irritant, even though one irritant, say bacilli, may act more readily than other irritants.

In view of the demonstrated fact that simple injuries of any kind can excite a tuberculosis, but only in certain individuals and tissues, it is evident that tubercularization is determined by the kind of soil and not by a specific irritant. *Tubercle should therefore be defined as being an inflammatory new formation in a specific individual or tissue.*

What is the place for tubercle in pathology? The anatomical criterion for tubercle is a granulation tissue, made up of lymphoid or epithelioid cells, which, on account of deficiencies in the soil, does not undergo any higher organization, nor tend to heal, but tends to form nodes and undergo cheesy change. Under favorable circumstances it may heal through fibroid change. The elements of tubercle tissue may spread by continuity of structure to surrounding parts, and occasionally tend to the production of metastasis, distributing themselves by means of the lymphatic system principally, and rarely by blood-vessels; and may generalize themselves through the whole body, forming miliary nodes or tubercles.

This miliary eruption of tubercle appears to have the same relation to the primary tubercular growth as the secondary metastatic cancer eruption has to the primary cancerous growth. As in cancer, the elements of tuberculosis may be arrested temporarily by the lymphatic glands governing the affected region.

In tuberculosis, lymphoid cells form the nodes; in cancer, epithelial cells. While secondary cancer nodes are, as a rule,

much larger than tubercle nodules, on account of the well-known great proliferating power of epithelium, it is also a fact that cancer may appear as a miliary carcinosis, expressed by minute nodules not distinguishable macroscopically from miliary tuberculosis. Cancer is proved to be a local disease. It is not contagious. It is infectious only to the individual who is affected by it—i. e., it is self-infectious. And so is tubercle, in every respect, a local, self-infectious disease.*

That local manifestation of tuberculosis in the lung, which is designated by the traditional name of pulmonary phthisis, forms perhaps nine tenths of all tubercular lesions, and hence deserves some special consideration.

I range myself with those who regard all forms of pulmonary phthisis as tubercular. There are only three or four lesions of chronic wasting disease of the lung which may be excluded from phthisis. These are atelectasis, or collapse from pressure of effusions; bronchiectasis, in which the enormous dilatation of the bronchi may lead to large cavities and atrophy of lung structure; primary fibroid changes; and abscess of lung. Yet all these lesions may become tuberculous from secondary inflammatory changes which usually follow.

The lesions that are known as catarrhal pneumonia, broncho-pneumonia, pneumonic phthisis, cheesy pneumonia, tubercular phthisis, and fibroid phthisis, are all manifestations of the one disease. Such a classification may be, however, entirely justifiable and useful for practical, clinical, and therapeutic purposes. Pathologically considered, phthisis is a local tuberculous inflammation of the lung, which may manifest itself in various ways, the appearances depending upon the duration of the disease, the mode of onset, and the constitution and condition of the patient. Lesions representing the different forms of phthisis, and their transition from one form to the other, are often seen in the same lung.

Virchow insists that nothing should be considered tubercular unless it shows true tubercle nodules, and hence he does not recognize cheesy pneumonia—or cheesy hepatization, as he calls it—as tubercular, although he does not object to the term phthisis for this lesion.

I was fortunate enough to attend several times the classical demonstrations on this point of Virchow, the father of the view of the dual origin of cheesy matter and phthisis; yet, from our present knowledge of what constitutes tubercle, I can not help interpreting all the forms of phthisis as of a unitarian origin. It is, after all, as Virchow himself says, only a matter of nomenclature. If we consider the presence of bacilli of Koch as the differentiating point between what is tubercular and what is not, we find that catarrhal and cheesy pneumonias are the most tubercular of all, because they contain, as a rule, more bacilli than any other forms of phthisis.

Although cheesy pneumonia, like all forms of phthisis, remains commonly a local affection, it is seen on the autopsy-table to give rise to miliary tuberculosis at least as often as any of the other forms of local tuberculosis.

We are, then, at present at the same standpoint in regard to

* Cancer and tubercle are considered analogous lesions, and classed with tumors, by a number of pathologists. This fact would not make it inconsistent to call tubercle an inflammatory product, as the distinction between inflammatory processes and tumor formation is a purely arbitrary one. Virchow has pointed out that the majority of tumors are purely inflammatory products (a statement antedated twenty years by Professor S. D. Gross). A few years ago I made the question of the etiology of tumors a subject of careful personal study, which I yet continue, and I am forced to the conclusion that *all* true tumors are inflammatory products, and that no line of distinction can be drawn where the process which we call inflammation ends and where tumor formation begins.

the character of tubercle and cheesy matter as Laennec (1819); and it is indeed perfectly reasonable to suppose that any cheesy matter found in a scrofulous person or animal is tubercular. Of course, it is evident that tuberculosis of the lung is usually accompanied by simple inflammatory products, such as organized connective tissue (chronic phthisis), or unorganized croupous and catarrhal exudates (predominating in acute phthisis), which may undergo rapid necrotic and purulent changes, resembling cheesy material. For the latter products the name "coagulation necrosis," as applied by the Heidelberg and Leipzig people, may be employed. Tubercle bacilli are commonly found in this coagulation necrosis. True tubercular cheesy matter should, I think, be considered only that product which is derived from the breaking down of previously well-organized tubercle tissue.

I need not refer to the details of the manifestation of tubercle in the lung, as these are too well known. But I would like to remark here that those small whitish or gray nodules, usually of somewhat irregular shape, which are seen more or less densely scattered throughout the parenchyma of lungs affected by phthisis, are not milary tubercles, but minute foci of broncho-pneumonia.*

These minute broncho-pneumonic foci take their origin from tuberculous matter disseminated by means of air-passages, as explained before. *Miliary* tuberculosis of the lung distributes itself by means of the perivascular lymphatics, is very rarely accompanied by catarrhal changes or hepatization, and rarely arises from a primary tuberculous focus of the lung itself; it is, as a rule, a part of general tubercular disease.

The Predisposition.—Having shown that for the production of tuberculosis we need a special soil, and that the irritant is only of secondary significance, some inquiry into the nature of this soil is necessary.

The question of the predisposition to tuberculosis, as it stands at present, must be considered from three aspects:

1. The clinical aspect.
2. The anatomical aspect.
3. The bacteridian or parasitic aspect.

The consideration of the clinical aspect of the predisposition to tuberculosis is invaluable, as it rests mainly on actual observation, on demonstrated clinical facts, and on conclusions drawn from statistics.

From time immemorial a clinically well-defined condition of the system, known as the strumous diathesis in its various forms, has been recognized. This condition will be considered later on.

There are a number of ailments which, from the experience of clinicians, are known to have a great, direct or indirect, influence in the development of general tuberculosis and pulmonary phthisis; or are known to create conditions of the system that predispose to this malady. Such are syphilis, inflammation of serous membranes, bronchitis, croupous pneumonia, diabetes, the exanthemata, especially measles and typhoid fever, deformities of the skeleton, rickets, cerebral and spinal diseases of various kinds, dyspepsia, the puerperal state, uterine diseases, prolonged nursing of children, onanism, change of climate, continuous loss of sleep, distress, etc.

That exhaustion, exposure, the deprivation of food, and other hardships of campaign life, etc., are prominent etiological factors in the production of pulmonary consumption is learned from the accounts of military surgeons, who have observed among young, robust soldiers a remarkable increase in the morbidity and the mortality of phthisis during and immediately

after the close of a war. Such observations were made in the Franco-Prussian and Turko-Russian campaigns. The fact that consumptive soldiers are not allowed to enter upon a campaign (certainly not in Germany and Russia) excludes here the probability of contagion.

Statistics also show the remarkable prevalence of phthisis in persons of certain occupations, such as stone-cutters, miners, cigar-makers, weavers, telegraph operators, book-keepers, and persons engaged in certain other occupations of a more or less sedentary nature. It is more natural to suppose that the disease or the predisposition to it is created by the character and the conditions of the occupation than that a contagion should affect preferably shoemakers, miners, or soldiers in the battle-field. Again, in most phthisical patients the beginning of the disease can plainly be attributed to an exposure, to a "cold."

On the other hand, there are pathological conditions or diseases which appear to prevent the development of phthisis and tuberculosis in general. It is an established clinical fact that phthisis is extremely rarely, if ever, associated with mitral heart disease; and, from my own observations, I believe that phthisis is rarely coincident with tumors. For the latter circumstance I can offer no explanation; nor is there any statement to this effect in literature. Rindfleisch has suggested that heart disease prevents the development of phthisis by inducing repeated slow congestions of the lungs, these congestions producing an overgrowth of the muscular tissue of the bronchioles and air-vesicles, which thus gains strength for repelling the exudates following inflammation. If tuberculosis were depending upon a contagium for its development, neither heart nor tumor disease, nor any condition of the organism, could ever prevent its occurrence.

All the clinical facts above referred to prove definitely the necessity for a predisposition for the development of tubercular disease, and militate against the necessity of a contagium.

The anatomical aspect of the question—the morphology of the soil in which tubercle develops—is the most important aspect.

Beneke* tries to explain the disposition to tuberculosis by a disproportion between the size of the heart and blood-vessels and other organs and the bulk of the body.

Schottelius† made recently some interesting observations concerning the mode of termination of the smallest bronchioles and their relation to the lung acini in different animals. He found that in the carnivora the entrance of the bronchioles into the acini presented very small apertures, so that the air-vesicles were not easily accessible to irritants; while in the herbivora the terminal bronchial terminations were quite wide, thus permitting the free entrance of irritants. He states that in man the bronchial terminations congenitally approach sometimes those of the carnivora, and sometimes those of the herbivora. In the latter type he believes he has found an anatomical explanation for the predisposition in some individuals to pulmonary tuberculosis.‡ Weigert, of Leipzig (one of the most enthusiastic germ-theorists), properly remarks, upon the observation of Schottelius, that it does not explain the predisposition, as the same animals will react, upon the introduction of the "poison of tuberculosis" into any other part of the body, where the bronchioles do not come into play.

My own studies upon the minute anatomy of the tissues of man and of animals predisposed to tuberculosis extended over

* "Die erste Ueberwinterung in Norden," Norden, 1882.

† Virchow's "Archiv," vol. xci, 1883.

‡ The method of investigating this condition is not without interest. The vesicular structure of the lung was injected, through the bronchi, with a resinous melted mass, which, on cooling, presented molds of the bronchioles in connection with their characteristic infundibula and acini.

* See, in connection with this, the excellent studies of W. H. Mercur, from the pathological laboratory of the University of Pennsylvania, published only in abstract form in the "Phila. Med. Times," July, 1883.

a large amount of material, and gave results which, to my mind, satisfactorily explained this condition. These results I announced at a meeting of this society in October, 1882.

The anatomical peculiarity observed in either man or animals, be it inherited or acquired, I first showed to be, briefly stated, as follows: All the tissues of the body approach somewhat an embryonal type; they are peculiarly rich in nuclei and young cells, and the lymph-spaces of the connective tissues are narrower, fewer in number, and show a great many more cellular elements in the serofulous than in the non-serofulous. So far, subsequent observations of others agree with mine. Objections are raised only as to the direct relation between these structural peculiarities and tuberculosis. Here I must state that I only suggested, and never asserted, the necessity of such a relation. It is quite possible that there are some other and more striking peculiarities in the morphology of serofulous animals yet undiscovered. This much I can, however, reassert to-day: that tuberculosis usually ensues, when a simple inflammation is set up by any kind of injury, in animals with the structural peculiarity which I have described; but tuberculosis can not be produced in animals that do not have this structural peculiarity, so far as my experiments show, unless the injury is inflicted upon serous membranes.

For the details of my researches in this direction, I must refer to my first paper upon this subject.*

Koch asserts that the structural peculiarities of the tissues which I described can have no ætiological relation to tuberculosis, because an animal not possessed of such tissue peculiarity—the cat—is easily inoculable by tuberculous material. Here I must differ from Koch, as in my experience with cats this is not the case; and, again, Koch brings no proof for his assertion, and I am unaware that he, or anybody else, has produced tuberculosis in a cat except by inoculation into some serous cavity. That inoculations into serous membranes prove nothing for tuberculosis, as I have shown conclusively, Koch still seems to fail to see. But here is a way in which cats may become tuberculous, with or without the bacilli. In one instance we kept one of the cats in a close box, deprived of liberty, good air, the comforts of life, motion, and sufficient food; she also had been inoculated with diphtheritic material eight months previously, but had recovered. After the lapse of a year the cat was set free, but was accidentally killed, and was found to be affected by general tuberculosis in a high degree.

This, in my opinion, corresponds fully to the conditions in which a healthy young woman is placed, and finally becomes serofulous, and then tuberculous, from a simple cold, after being the faithful nurse for two years of a consumptive husband.

On the other hand, there is full reason to believe, as it is in accordance with experience, that young serofulous persons, under proper conditions, may become normal individuals—i. e., lose or outgrow the predisposition to tuberculosis. (I have dwelt upon this in my first communication on this subject.)

The serofulous habit, and, consequently, also phthisis, may skip a generation, and does not invariably embrace all members of a family. It has been observed that parents may have at first healthy children without any vice, who grow old well; and subsequently the same parents, without being phthisical (but, perhaps, otherwise becoming deficient in health), may have other children that exhibit a full serofulous habit. But even the reverse has been observed.

It would be highly desirable if physiologists would furnish some experimental observations on the circulation of the plasma in the lymph-spaces. This is, to my mind, a circulation or movement of vital juices in the tissues, which, for the well-

being of the individual, is of an importance next to that of the blood. These important channels, the lymph-spaces, are known to regulate the blood-pressure, carry and breed food (white blood corpuscles) for the tissues, lubricate tissues, and relieve the body, if any of its parts are damaged by injury of any character, of inflammatory exudates, dropsy, etc. These channels are nearly blocked up, nearly useless, in the *serofulous*, and hence can not perform their functions, and thus modify materially the condition and the fate of the individual in case of disease.

The term "*serofulous*," which I retain for describing the above-stated anatomical peculiarity of animals and individuals, is as good as any other term; moreover, it is known by all as designating the "predisposition" to tuberculosis. *Serofulous* should be called a *condition* and not a disease, as it has its (a natural) hereditary and widely distributed type in man, and its homologue in some normal animals (rabbit, guinea-pig, etc.). It must be remembered that the serofulous individual acquires certain lesions—such as enlargements of lymphatic glands, cold abscesses, caries, long-standing catarrhs of various kinds, skin eruption, and certain deformities of bones—only under the influence of injuries, or of the same agencies which, in the non-serofulous individual, lead to transient and curable affections.

Virchow designates simple, permanent enlargement (hyperplasia) of lymphatic glands, with or without cheesy change, "*serofulous*," in contradistinction to "*tuberculous*" lymphatic glands, which contain milium tubercle nodes (heteroplasia), and which also undergo cheesy change.

There is nothing called "*serofulous*" or "*serofulosis*" which by others is not also called "*tubercle*" or "*tuberculosis*." There are, strictly speaking, no serofulous products, but only tuberculous products. The traditional term "*serofulosis*" is variously used and interpreted, although it is not evident that any one means by it anything anatomically well defined.

Others take matters easier, calling everything *tuberculous* that contains tubercle bacilli, and calling serofulous all cheesy matters in which bacilli are absent.

There is still a third aspect of this question, viz., the parasitic or bacillary theory of the predisposition to tuberculosis. As I mentioned in the earlier part of this paper, Baumgarten, Marchant, and several others have recently stated that not only tuberculosis, but even the predisposition to tuberculosis, is to be explained by the susceptibility of an individual to bacilli! Under this hypothesis the inherited serofulous tendency in individuals is created through the mediation of the bacilli. It is supposed that the bacilli or their spores may be conveyed to the ovum by the organism of the mother, or *in utero* by the spermatozooids of the father. Furthermore, they say, inheritance is to be explained in no other way than by a bacillary infection of the infant through the milk of the nursing mother, and by subsequent living together of children and phthisical parents. We may exclude such view altogether from consideration, as it has not been proved. Besides, it is not in accordance with facts from observation. It is as contrary to biological laws to accuse parasites of the transmission of a predisposition to tuberculosis as it would be of that of epilepsy, etc. Hence we may dispose of such view as an unfounded, absurd hypothesis.

I am not opposed to the germ-theory of disease where it has its well-founded and proper application. Bacteridian studies have contributed largely to our knowledge of a certain class of pathological processes and lesions. But misinterpretations of the significance of bacteria—bacillary speculations, without occasion for them and without any proper application to the subject—are a check to the progress of medical science. The question of the predisposition to and the cause of tuberculosis demands a great deal more of solid pathologico-anatomical and

* Loc. cit.

experimental studies; it can by no means be regarded as settled, and least of all through the discovery of a bacillus inhabiting necrotic tubercular tissues.

Tuberculosis, without Predispositions, due to Inflammation of Serous Membranes.—For some years I have felt much interested in the question whether or not simple inflammation of serous membranes could lead to tuberculosis in the non-scrfulous—that is, in persons who have no family history of tubercular disease; and I would like to ask the opinion and experience of the members of the society upon this question. It is well known that there may be primary tuberculosis of serous membranes, producing secondary inflammations; and, on the other hand, tuberculosis secondary to adhesive pleurisy or peritonitis is also common in serous membranes. The general belief, however, is that, whenever tubercular disease in either case occurs, if not secondary to phthisis or tubercular disease elsewhere, a stromous or scrfulous condition is required.

Traumatic injuries of joints are known to lead often to fungoid (tubercular) synovitis and general tuberculosis occasionally in individuals with good family history. Simple injuries of the eyeball (the anterior chamber, as well as joints, is lined by serous membrane), under conditions as above stated, have also been known to lead to tuberculosis, as recorded by Wolfe ("British Medical Journal," March, 1882); Gradenigo ("Annales d'oculistique," 1870).

Dr. M. Litten,* of Berlin, was the first to publish some accounts which demonstrate that miliary tuberculosis may be caused directly and primarily by pleurisy and inflammation of other serous membranes in persons with no phthisical history, and without any cheesy masses being formed in any part of the body. In his (Litten's) experience this was particularly the case when there was a rapid reabsorption of the exudates in case of chronic pleurisy, or if repeated removal of the fluid of a hydrothorax or ascites by tapping had been performed. He records several well-studied cases of that kind, accompanied by autopsy records. Litten's observations at no time, however, received the attention they well deserved.

Not only clinically, but also pathologically, this part of the tuberculosis question is rather neglected. In text-books of pathology the occurrence of primary tubercle in adhesive bands is incidentally mentioned, but no special consideration is devoted to its ætiology and manifestations.

Upon the autopsy-table I have repeatedly met with subjects with exquisite primary tubercular peritonitis, pleurisy, or pericarditis, which, upon inquiry into the history of the cases, failed to reveal any phthisical or scrfulous history. The products of these inflammations were often plastic in character, not unlike those of fungoid synovitis. The appearances sometimes present themselves particularly strikingly in the peritoneum; all the viscera may be glued together by plastic material into a solid mass. The omentum is usually retracted and matted together into a solid cord or mass, which, lying parallel with the transverse colon, reaches across the abdominal cavity, and may have a thickness of from two to four inches; the mesenteric and other lymphatic glands are usually normal, but sometimes in advanced cases may be much enlarged and more or less cheesy. The perfect absence of any cheesy focus in the body is, however, often a conspicuous feature in these cases.

Some pathologists deny the tubercular nature of these formations and of the flat nodular masses which cover the serous surfaces in these cases. It is true that fibroid changes predominate in these formations; but numerous tubercle nodules, with all the necessary attributes, epithelioid and giant cells, and necrotic changes, were plainly seen in all cases which I had occasion to examine. Secondary miliary tubercles of quite recent date are also found thickly strewn locally in these parts, and may or may not be seen in the lungs and other organs. As a rule, there is more or less ascites in these cases. My colleague, Dr. E. O. Shakespeare, has recorded similar cases, and Dr. Morris Longstreth tells me also that he has seen and studied such cases. Dr. Mitchell Prudden ("Medical Record," June 16, 1883) describes an allied case.

In chronic adhesive pleurisy there occur similar primary tubercular formations in the organized plastic exudate, which in some cases give rise to secondary (miliary) tuberculosis of other organs. The lungs may be perfectly normal in all parts, and show only peripherally, just below or bordering upon the pleura, some indurations of gray color made up of recent tubercle tissue. These young tubercle infiltrations are in some cases seen to have penetrated into the substance of the lung, in a pleuropneumonia or dissecting pneumonia directly from the old tubercular masses of the adjacent pleural membrane. I have also examined several cases of plastic adhesive pericarditis, and found the plastic vegetations in this lesion to contain tubercles; two of these had coincident pleuritic lesions.

Cases which have come under my observation during the last eighteen months—i. e., since the opening of the bacillary campaign—have, of course, been carefully examined for bacilli, and the results may be summarized as follows: Bacilli were found in most of the lesions, if the tubercular disease of serous membranes was accompanied by cavities and cheesy masses in the lung, or by tubercular ulceration of the intestines, and if cheesy changes in general were prominent; but no bacilli could be discovered, even after repeated and careful search, in any of the lesions of four cases of primary peritoneal and pleuritic tuberculosis examined. In none of these latter four cases were there any conspicuous cheesy changes in any organ, and no cavities or marked hepatizations in the lung, and no intestinal ulcers, although in two there was slight pulmonary miliary tuberculosis. These cases will be recorded in detail in a future publication.

I have also seen several cases of primary tubercular pleurisy and pericarditis, and a few of primary tubercular peritonitis, in the pathological institutes of Virchow in Berlin, and of von Recklinghausen in Strassburg. I questioned these foremost men of pathology concerning the ætiology of these lesions. They, as well as Rindfleisch, of Würzburg, told me personally their opinion, stating their firm belief that these lesions often directly originated from simple chronic inflammatory changes, without the agency of any cheesy focus, or any specific agencies whatsoever.

Birch-Hirschfeld also states, in his classical pathological work (page 183), that "nearly every exudative pericarditis and pleurisy leads to a local tuberculosis, if it takes a chronic course."

How often primary tubercular lesions of serous membranes occur in non-scrfulous persons, and whether this is the only form of tuberculosis in this class of persons, is, of course, a matter of speculation until thorough statistics and careful studies are made in this direction. Nevertheless, it is a demonstrated fact, as I will show further on, that primary tuberculosis can be produced in the peritoneum of animals, like the dog, which are proved not to have any scrfulous tendency. I have seen this myself, and seen O. C. Robinson, in my laboratory, succeed in this experiment by the introduction of simple irritants into the

* M. Litten, "Sammlung klin. Vorträge," No. 119. "Ueber acute Miliartuberculose," 1877. For further references, see "Wiener med. Presse," No. 36, 1882; "Charité Annalen," vol. vii, Berlin; "Kranksheiten der Respirations-Organe," in Virchow's "Handb. der spec. Path. und Ther." vol. i; Virchow, "Geschwülste," vol. ii, p. 725, etc.; also, Formad, "Transactions of the Philadelphia County Medical Society," and "Transactions of the Pathological Society," for 1882-'83.

peritoneal cavity. Koch also never succeeded, even with the bacillus, in producing tuberculosis in the dog, except when using the peritoneal cavity or the anterior chamber of the eye (which is also a serous sac) as a point for inoculation.

Here is room for hypothesis. I would prefer to believe that tuberculosis could occur only in scrofulous persons, as this would better agree with the *scrofulous anatomy*. It is, however, possible that a scrofulous anatomy of the tissues may be artificially established by the blocking up of the lymph-spaces of the serous membranes by fibrin and molecular *débris* suspended in the serum which is being reabsorbed. This would then be a mechanical process, and not one of infection. If an inflammation occur in serous membranes, resolution becomes difficult through the peculiarity of the exudate. This is fibrinous mainly, and, forming extensive, usually permanent organized deposits, it impairs the function of serous surfaces quite materially; the reabsorption of new exudates is probably sometimes entirely impossible. Thus conditions may possibly be created in serous membranes not unlike those of scrofulous tissues; and simple irritants, perhaps the fibrin, may induce in them a similar reaction.

Question of Contagiousness; Clinical Aspects.—The idea of the contagiousness of tuberculosis is not new, and, like other unfounded views in medicine, it has oscillated, as all fashions will, from one extreme to the other for many generations. At present it is entertained by a number of scientists and by a part of the profession. This view has called forth, from time to time, a number of researches whose results were either *pro* or *contra*. I will refer to these subsequently.

Of late, it appears that the belief in the contagiousness of tuberculosis has won considerable ground, not so much on account of accurate observation as on account of Koch's discovery of the *Bacillus tuberculosis*.

Another element which seems to have had an influence in this direction is the fact that certain experimenters, formerly believing, from their own experiments, that tuberculosis was non-contagious, were led, later on, to change their opinions on account of the results of subsequent experiments. These latter experiments will, however, be shown not to be conclusive.

Before discussing the merits of the bacillus question, I would like first to consider the question of contagiousness from clinical grounds; and, should it be proved that tuberculosis is not contagious, then the necessity for a contagium surely falls to the ground.

According to the observations of the most prominent clinicians who have paid special attention to this matter, there is not a single authenticated case of tuberculosis as a result of contagium on record. Among scores of experienced men who deny thus the contagiousness of tuberculosis it is sufficient to mention the names of Virchow, Recklinghausen, and Stricker, in Germany; Gull, Williams, Watson, Paget, Humphrey, and Richardson, in England; Bennet, in France; and Hiram Corson and Traill Green in our own country—all men of close observation, with ripe experiences reaching over thirty to fifty years.

The statistics of the large Brompton Hospital for Consumptives, for thirty-six years, with regard to the resident officials, compiled by Dr. F. Williams (quoted from the "Lancet," 1883), show that of four resident medical officers, one of whom had served twenty-five years, none had any lung disease; of six matrons, none were consumptive; of 150 resident clinical assistants, eight became consumptive and five died, but in only one was the disease developed during residence at the hospital. Since 1867, of 101 nurses, only one has died from phthisis, and that after leaving the hospital. Before 1867, six died, three of these of phthisis, but only one became so while resident, and she had a consumptive sister. She died thirteen years after first joining the hospital, but was not there the whole time. Of thirty-two

gallery maids since 1867, none developed phthisis while at the hospital. Of twenty house-porters, five died, but none of consumption. Non-residents: Of nine secretaries, three were threatened with lung disease, but recovered. Of twenty-two dispensers, seven died, three of phthisis, one while at the hospital. Of four chaplains, three died, none of phthisis. Of twenty-nine physicians and assistant physicians, eight died, none of phthisis. At the Chest Hospital, Victoria Park, there have been five resident medical officers during about the last fifteen years; all are alive and well. Two matrons, neither consumptive. There were two clinical assistants appointed every three months; none known to have developed the disease at the hospital. One nurse out of fifty or sixty in the last few years became consumptive while at the hospital, and she died after a year's illness.

An ingenious plan to decide the question of the communicability of phthisis was instituted by the British Medical Association by establishing the Collective Investigation Committee. This committee sent out questions relating to this subject to all the members of the society. Of 1,028 replies received, 673 negated the idea of a contagium, while 261 replies favored it. According to these statistics, there is a manifest majority in favor of the non-contagiousness of phthisis; yet such a plan is unsatisfactory, for the answers may be of unequal value, as their worth must be estimated in proportion to the experience and authority of the sender.

Not without interest is the observation of Professor Corradi, of Pavia, who noted that out of 133 families in which he had cases of consumption, in only twenty-five of the families were there more than one member of the family ill of that affection.

There is no proof whatever that tuberculosis is conveyed from person to person by contagion. Seeming exceptions to this assertion can almost always be accounted for in some other way.

The assertion that the wife may contract the disease from the husband I have pointed out, in a former paper, to be untenable; and I have also indicated that a predisposition to scrofulosis may be acquired from the unwholesome mode of life led, of necessity, by such individuals. Besides, it is established statistically that nearly one third of all deaths occurring in middle life are due to phthisis. In view of the frequency with which this malady occurs, intermarriage between scrofulous individuals may be almost as common as between non-scrofulous ones.

The view taken that children become scrofulous by contagion from phthisical parents may be met by the fact that instances have occurred where a number of young children of phthisical parents were early removed from their homes and distributed among healthy families, and yet all, sooner or later, became phthisical.

Healthy persons have even been fed on bovine tuberculous material (which is considered identical with human tuberculous material), and have thriven on it, as is proved by the interesting feeding experiments made upon man and recorded by Schottelius (Virchow's "Archiv," vol. xci, 1883). The circumstances which led to this experiment were as follows: In Würzburg the sale of meat affected by pearl disease or bovine tuberculosis is permitted, but, as some opposition to its sale once arose, a community of country people agreed to use exclusively tuberculous meat, on account of its cheapness and in order to prove that it was harmless. From October, 1867, to November, 1868, forty-nine tuberculous heaves, with well-pronounced lesions, were consumed by these people while they were under the supervision of the district physicians. In many instances the meat was even eaten raw in consequence of habit. Ever since then those people have continued the use of tuberculous meat, and thus far no bad results have been noticed; in fact, the record says that the people referred to are unusually healthy.

Lectures and Addresses.

THE CARTWRIGHT LECTURES

ON

METHODS OF STUDYING THE BRAIN,

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 6, 1884.

By BURT G. WILDER, M. D.,

PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

LECTURE II.

Methods of Manipulation: Removing, Preserving, and Examining the Brain.

SINCE he is permitted to clean scrupulously the abdominal muscles before examining the viscera, the average first-year medical student is at least consistent in deferring the removal of the organ of the mind until he has carefully dissected the muscle which wrinkles the forehead. He lacerates the brain with saw and chisel; tears it in the effort to save the sacred skull-cap entire; injures it yet more in the process of extraction, and places it upon a flat surface, where its own weight completes the rupture of delicate connections and hopelessly distorts its shape. Here he leaves it, perhaps for a day or two, probably drying, and possibly freezing or decomposing, according to the temperature. He then transfers it to a basin or pail, covers it with strong alcohol, notes with satisfaction that the surface rapidly hardens, feels sure of finding out all about the brain, and sees himself a future neurological expert, or even an asylum superintendent. In due time—that is, when not engrossed with other and usually far less important organs—armed with his “Gray” and a large knife, he succeeds in identifying the cerebellum, the optic chiasma, the orifice left by tearing off the “pituitary body,” and the pons Varolii, which therefore has not proved to be in his case—as he knows it has with some of his fellows—a veritable “pons asinorum.” He also recognizes the fissures of Sylvius and Rolando, but the pia has dried upon the hemispheres, and the effort to detach it creates so many undescribed depressions that the detailed study of the convolutions is left for a more favorable occasion. Lifting the occipital lobes, his fingers presently find their way into cavities which must be the “descending horns of the lateral ventricles,” thus practically refuting the opinion of certain “theoretical” anatomists that there is no such thing as a “great transverse fissure” until artificially produced. He then slices the brain *secundum artem*, and so great is his pleasure in demonstrating the “centrum ovale majus” that he is not seriously disturbed at the presence of an unexpected rent in the callosum and of an irregular orifice on each side. Continuing his operations, however, he finds the interior of the brain little more than a mass of nearly homogeneous pulp; at first he fears that the alcohol was too weak, but, when satisfied upon this point, suspects that the names in the books have somewhat the same significance as those of the heavenly constellations, modestly admits that he may not be sufficiently advanced to study the brain,

and resolves that, when he is personally prepared for this branch of inquiry, his *armamentarium* shall consist not of a scalpel, but of a spoon.

Not only does the foregoing fairly describe what often happens, but there is little reason why it should not happen always. In what manuals of descriptive or even practical anatomy are there given adequate directions for the removal, preservation, and dissection of the brain? In what medical college do these matters form a topic of extended instruction? In what medical museum are they exemplified? How far is the average graduate prepared to make a necropsy for the sake of determining any critical encephalic question?

The fullest directions known to me are given in the “Practical Anatomy” by Heath, edited by Koen; whether, in my judgment, they are sufficiently full may be inferred by a comparison therewith of the “Directions for the Removal, Preservation, and Dissection of the Brain of the Cat,” in the “Anatomical Technology” (Wilder and Gage, 423–436, 450–457). The works of Quain and Allen give no directions at all, and, in the last edition by Gray, they are comprised within seven lines. The manuals of Delafield and Bevan Lewis have rather a pathological than a normal bearing, and certainly presuppose too much knowledge and skill upon the part of the reader.

Medical students seem to be credited with an inherent notion as to the way of removing a brain, as if the head were merely a nut to be cracked and emptied; but here the simile ceases, for the shell is prized and preserved, while the kernel is too often either decayed or unappreciated. Has it never happened in a medical school that the exposition of the structure of the noblest and most intricate organ of the body has occupied less time than was devoted to the description of a few ligaments and bones? Has it not sometimes consisted in taking a brain, which was removed in twenty minutes (less than should be spent upon a cat’s), dashing it upon the table with an air of familiarity such as the baker displays toward his lump of dough, and hewing it into incongruous slices or tearing it to display artificial conditions? * Has it never resulted that the principal acquisition of the students therefrom has been a profound conviction of the self-confidence of the demonstrator?

Are there not, in large cities of the United States, museums connected with populous medical schools, yet containing, perhaps, a few animal brains, but none displaying the normal human organ; perhaps a series of encephalic tumors and abnormalities, but no normal structures; perhaps even plenty of skulls, but no brains at all?

If the prevalent customs are what they should be, how is it that the following sweeping assertion of a distinguished medical anatomist has stood upon the pages of the leading American medical quarterly without even an attempt at refutation?

“In our colleges . . . the only point of technic the

* The article “Anatomy” in the last edition of the “Encyclopædia Britannica” (i, 876) seems even to acquiesce in the present condition of things as beyond remedy: “In taking the brain out of the cranial cavity, this commissure [the mediacommissura] is usually more or less torn through, and the cavity [diacœlia] is consequently enlarged.

medical student is taught is how to use his knife and forceps in dissection. He is given no instruction in the art of exploring viscera or gland-ducts, the methods of taking out the brain or spinal cord, the preservation of anatomical specimens, or the thousand and one things that he needs in making an autopsy or in preserving specimens. Judging from the condition in which specimens are often presented for inspection at our medical societies, it is evident that not one physician in a hundred knows the use of alcohol as a preservative."—The "American Journal of Medical Sciences," January, 1883.

Why, finally, in the case of that brain upon whose configuration alone it was thought by some might depend the decision as to whether there had been committed two murders instead of one, why was it possible that this infamous yet precious brain should be removed hastily and, by the ordinary barbarous method, weighed in a grocer's scales,* neither photographed nor even sketched, and, in short, as regards its gross anatomy, so inadequately examined as to neither advance science nor establish justice? Not the brain of the most insignificant cat should be so lightly dealt with as was the human brain whose condition, whether cause or merely concomitant, presented the most solemn psychological problem of modern times. Whatever may have been the reason for the absence of proper facilities for examination and for the neglect of such opportunities as may have existed, since the determination of Guiteau's insanity was in no degree aided thereby, for the credit of the medical profession of this country it would have been better that his brain should not have been removed at all.

Old ways are not necessarily good ways, and sometimes it is discovered that time-honored customs have nothing to recommend them save their antiquity. Notwithstanding, therefore, its archaeological respectability, I am forced to characterize the well-nigh universally employed method of getting at the human brain for macroscopic purposes by "inserting a strong hook and giving a quick jerk" as anatomically futile and artistically brutal, alike disrespectful to the organ concerned and to the operator as a member of a learned profession; upon the whole, it is less admirable than the splitting of a pig's skull by the butcher for extraction of the brain as an article of food.

The principal features of the methods employed in the Anatomical Laboratory of Cornell University for the macroscopic study of the normal brain are as follows:

1. The initial determination, if possible, of the use to be made of a given brain.
2. The concentration and preservative effort upon the parts especially desired, and, in some cases, a reduction of the mass to the region containing these parts.
3. The exclusive employment of alcohol as a preservative agent.
4. The maintenance of a low temperature during all preservative processes.
5. The injection of alcohol steadily for from one to ten days (continuous alinjection †) into the arteries so as to harden the brain *in situ*.

* The "Medical Record," July 8, 1882, p. 53.

† Since *aldehyde* is generally accepted as a legitimate abbreviation

6. The demonstration of the forms of the *cœliæ* ("ventricles"), and the contour of their parietes by the injection into them of alcohol, or of some mass capable of solidifying into a cast.

7. The systematic and intentional mutilation or even destruction of the skull for the sake of the brain.

8. The removal of the adult calva, after the usual circular incision, by hemisection a little laterad of the mesen.

9. The exposure of the brains of fetuses and small animals by means of nippers, the trephine, and the dental engine.

10. The avoidance of all pulling upon the brain, either active or from its own weight, by the observance of care in all manipulation, and by the constant support of the organ in brine.

11. In general, a treatment of the brain in a manner commensurate with its complex structure, its high office, the value of the information to be gained from it, and, last though not least, our own self-respect and consideration for our patients; for he who is habitually rough with the dead is certainly in danger of occasional disregard of the living.

In the following amplification of the methods just named, the scope of the present course and the lack of time confine me to the more novel and important features. Some account of them has appeared in the "Transactions of the American Neurological Association" for 1883 ("Journal of Mental and Nervous Disease," July, 1883, 81–83), and they were briefly described at the meeting of the Society of Naturalists of the Eastern United States, December 28, 1883. Fuller details are reserved for subsequent publication.

Lateral Hemisection of the Calva.—The scalp is divided, as usual, by a transverse incision from ear to ear, and the flaps are reflected as far as possible either way. A cord is carried around the head from about 1 cm. dorsad of the occipital protuberance, at a level with the ends of the scalp incision; if the string be kept in the same plane, it will cross the forehead 1.3 cm. dorsad of the brows. This string is held steadily in place, and a light cut or black mark made along its entire length. With this as a guide, a firm, clean cut to the bone is carried about the skull, and the saw—which should be straight and sharp—is used along this cut. The operator should stop at frequent intervals and ascertain whether he has penetrated the skull, by means of a moderately sharp point like that of the probe-end of the "tracer."* The bone should be *completely divided*, excepting at four points, say at or near the four "corners" of the head. The string is then carried over the head about 1 cm. dextrad of the mesen,† a guiding cut made as before, and the calva hemisected along this line. If the dextral piece does not readily come away after division of the two corners, a small, narrow-bladed palette knife‡ is passed between the dura

of alcohol *aldehyde* enters, there seems to be no *a priori* objection to *alinjection*, *alinject*, *alinjected*, etc., as a single word equivalent to *alcohol injection*, etc.

* "Anatomical Technology," Fig. 17.

† So far as concerns the brain, the hemisection may be made as well upon the left side, but, in accordance with the general plan of mounting skeletons, especially of animals, so as to display the left side, if either, the division of the calva is less obvious when made upon the right.

‡ This was suggested to my friend, Professor S. H. Gage, who, in

and the calva first in the temporal region, where the latter is usually thin. *Neither now nor at any time is force to be used.*

The dural adhesions along the superior longitudinal sinus are now within reach, and may be loosened by the palette-knife or with a sharp edge if necessary, and, on division of its two attached places, the left side of the calva is readily removed. The two parts of the calva may be wired or cemented together.*

Supporting the Brain in Brine.—So far the brain is fully supported by the dura, which, if proper care has been used, has not been divided by the saw. When the dura is removed, the brain is sure to tear by its own weight unless constantly supported. The body is therefore raised to the level of a large pan or earthen dish full of brine, about twenty-two per cent. Good dairy salt should be used; if the salt is not clean, the brine is turbid and obscures the dissection. If it is desirable to avoid the spilling of brine, the vessel containing it may stand in a pan or tray. With the palette-knife the dura is separated from the skull as far as possible on all sides. In this way, by a little care and by using a narrow, sharp-pointed knife for severing the olfactory filaments *ectad of the dura*, the *Lobi olfactorii* may be removed entire. The dura must be divided along the margin between the anterior and middle fossæ and wherever its adherence to the *basis cranii* is very firm. The optic nerves are to be cut as soon as seen, and the infundibulum divided immediately afterward; if the hypophysis is wanted, it can be separately extracted after removing the brain. The subsequent steps in the operation would take too much space if described in detail, but, if the brain is constantly supported in the brine, there need be no trouble. When removed, its dorsum is still covered by the dura, and, for some purposes—as, e. g., the study of the base while fresh, and alinjection, either vascular or entocælian—it may be retained with advantage.

The Exclusive Use of Alcohol.—For primary immersion or injection, the alcohol is fifty to sixty-five per cent., and the strength is increased to ninety-five per cent., more or less rapidly, according to the size of the mass to be penetrated; with a small and thin-walled brain, like that of an embryo or *Necturus*, the full strength may be applied within six hours; with a large mass, as many days should elapse.

As examples of what may be done with alcohol, I show brains of cats, frogs, monkeys, and men, fetal and adult; it is difficult to see how brain substance can be firmer or more durable than these; one specimen, the half brain of a child at birth, has been in alcohol for nearly ten years, and seems to be as sound as ever.

In affirming that alcohol is an efficient preservative of nervous tissue for macroscopic study, I neither deny the usefulness of other agents nor claim that alcohol is altogether adapted for histological purposes. The trials of other liquids

fact, during my absence, had the first opportunity of removing a human brain by hemisection of the calva after I had determined to adopt this method.

* Spitzka has described briefly ("Trans. Am. Neurol. Association," as reported in the "Journal of Nervous and Mental Disease," July, 1883, p. 84) a method of removing the brain by sawing off only the back part of the skull.

in the anatomical laboratory of Cornell University have not been sufficiently extensive or systematic to warrant any generalization therefrom. Some of the other agents are cheaper than alcohol, but, when the latter is obtained free of tax (as it may be for any museum or educational institution, under certain regulations), the cost is slight.

The only valid objection to the macroscopic use of alcohol is that it bleaches the color of the cinerea so that the location and limits of the ganglionic masses are less easily traced. This very important information may, however, be obtained after thorough acquaintance with the general topography of the organ, by the examination of fresh brains or of specimens preserved in some other way.

How far alcohol will answer for histological purposes is not yet, I think, well determined. On the one hand, a recent manual of practical histology (Gibbes) states that it is efficient; on the other, Spitzka, as reported in the "Journal of Nervous and Mental Disease" (July, 1883, p. 84), declares the methods employed by me "absolutely unfit for histological and pathological purposes."

Pending the examination of brain tissue hardened as herein described, I can only add that there are reasons for ascribing some of the previous poor results to either the application of strong alcohol to a large mass, or the failure to maintain a low temperature while the alcohol is penetrating the specimen.*

The Low Temperature.—The value of this condition as an adjuvant to direct preservative agents is well known; indeed, an essential piece of laboratory furniture is a refrigerator of some kind. For some purposes an ordinary ice-chest, opening at the top, serves a good purpose; the chimpanzee, referred to further on, was fully preserved by continuous arterial alinjection while lying in such a chest for ten days. But all operations requiring a low temperature are more conveniently carried on in a cold closet or small room adjoining the laboratory. Such a place may be temporarily provided by inclosing a window and sufficient adjacent space by a glazed partition; during cool weather a sufficiently low temperature may be secured by simply opening the window.

Mesal Hemisection of the Brain, either before or after Removal from the Skull.—For the study of the fissures and gyri, and of all parts excepting such as lie directly upon the mesen (conarium, medicommissura, crista, etc.), the brain is well adapted if hemisected either before or after removal. Nor need the head be frozen in the former case. If the saw be sharp and the teeth not much "set," the falx may be split in two, and the mesal aspects of both hemispheres preserved. As this, however, requires considerable care, and the use of a sort of miter-box or macrotome (recommended by me 1873, *II*, 217), it is desirable, to insure the safety of at least one mesal surface, that the hemisection should be made 1 to 2 mm. laterad of the mesen, and the adherent portions of the opposite side of the brain removed afterward with a scalpel. Each hemi-encephalon is very easily removed from the skull.

If the brain has been removed entire, it may be hemi-

* Dr. W. A. Hammond has called my attention to his preservation of small portions of nervous tissue for microscopic examination by immersion in absolute alcohol in tubes surrounded with ice.—The "Psychological and Medico-Legal Journal," September, 1874, p. 169.

sected with a large and very keen and thin knife, alcohol being poured on it as the section is made. The brain should be steadily by an assistant, and rest on a bed of cotton in a long, deep pan of brine.

The hemi-encephalon is to be hardened while resting on its mesen upon a flat surface, preferably of glass. Since the bottoms of jars and dishes are rarely flat, the brain should rest upon a separate disc of glass which may be lifted from the vessel without touching the specimen. For two days the brain should be made to rise a little from the glass every few hours, in order to permit the access of alcohol to the mesal surface; then for a day it may be supported on its lateral aspect in a bed of cotton to prevent distortion.

If it is desirable to determine the precise relations of the fissures and gyri to the skull, a hemisected head may be placed in alcohol and access of the liquid to the lateral regions secured by trephining in several places and injecting alcohol entad of the dura.

Hardening the Brain in situ by Arterial Alinjection.—If not only the fissures are to be studied, but also the configuration of the whole brain is to be determined, the above-named method should be employed. In evidence of its efficacy, there are shown the brains of a cat, a marmoset, a chimpanzee, and a man thus prepared.

The injection of alcohol through the carotid arteries for the sake of preserving the brain was done by Professor Flower upon a man, and by—or for—Professor Owen upon a gorilla. From the published statements it does not appear whether the injections were repeated, and there is no reason to think that the flow was made *continuous*.

Before alcohol is injected, the vascular system should be cleared by the repeated injection of tepid water until what escapes from the veins is uncolored by blood.

A cannula is then secured in an artery leading to the brain; or, if it be desired to alinject the heart *in situ*, together with other parts of the body, one cannula in the portcava and another in a pulmonary vein, as was done with the chimpanzee and marmoset* above mentioned.

These cannulae are connected independently, or together by means of a T-tube and rubber tubing, with a reservoir of alcohol, which is set upon a shelf at a sufficient height to insure a flow, or raised and lowered by means of a windlass. The animal or brain should rest in a vessel into which the alcohol escapes as it flows from the veins or oozes from various surfaces, natural and cut. The same alcohol may be used over and over, its strength being restored or increased by the addition of fresh alcohol.

As soon as there is reason to believe that the brain is so far hardened as not to be distorted by its own weight, a part of the calva may be removed, as above described, and afterward the dura. This permits the direct access of the

alcohol in which the specimen lies, and any possible distortion may be corrected by the half of the brain which remains inclosed.

FIG. 40.—OUTLINE OF THE MESAL ASPECT OF THE BRAIN OF A CHIMPANZEE, hardened while resting on the base; reduced.

extension of the occipital lobes of the hemispheres 1 to 2 mm. beyond the cerebellum, when the head is supposed to be so

* Some of these photographs represent the brain before removal from the skull, and some before the removal of the dura.

* For the latter I am indebted to Dr. W. A. Conklin, Superintendent of the Menagerie in Central Park; for the former to Mr. A. E. Brown, Superintendent of the Philadelphia Zoological Gardens, and to Dr. H. C. Chapman, one of the Directors and formerly Prosector of the Zoological Society. It was supposed by Mr. Brown to be about four years old. Its weight, the day after death, was 6.7 kilograms (14 lbs. 13 oz. avoird.); its total length, with the legs extended as if standing, was 75 cm. (about 29.5 inches), and the spread of the aris 102 cm. (about 40 inches).

placed that the eyes look horizontally forward. There has been considerable discussion among anatomists upon this point, since the cerebellum is covered in man and not in the lower mammalia. I have never permitted myself to express or even form an opinion, because a brain removed in the usual way and hardened upon a flat surface inevitably loses its shape; indeed, the evidence of the nature and extent of this distortion is furnished by all the published figures of anthropoid brains which have come under my notice. In reproducing here the leading outlines of a figure of a chimpanzee's brain from the paper of an eminent American anatomist, and in asking a comparison between them and the similar outlines of the brain hardened *in situ*, I desire both to indicate the fact of the covering of the cerebellum and to illustrate the value of the method. That the comparison is made from no motive of unfriendly criticism may appear from the similar contrast between the human brain

hardened *in situ* (Fig. 42) and one which I prepared twelve years ago according to the method commonly employed.

(To be concluded.)

Original Communications.

ON THE VALUE OF INTERNAL ŒSOPHAGOTOMY IN THE TREATMENT OF CICATRICAL STRICTURE.

By HENRY B. SANDS, M. D.,

PROFESSOR OF THE PRACTICE OF SURGERY IN THE COLLEGE OF PHYSICIANS
AND SURGEONS, NEW YORK; SURGEON TO THE ROOSEVELT HOSPITAL.

(Concluded from page 157.)

The most difficult problem connected with the operation is that of exactly regulating the depth of any given incision. I believe that this can be done only by distending the stricture at the time when the knife is applied to it. On this principle I have devised the simple œsophagotome represented in the accompanying figure.

The shank of the instrument, which is fifteen inches and a half in length and four millimetres in diameter, is a flexible tube, made of narrow, spiral steel plate, secured within by two pieces of fine wire, in order to prevent stretching or separation of the spiral coil. The instrument is provided with a variable number of steel bulbs, each bulb being fur-

nished with a corresponding knife-blade. The bulb is firmly fastened by a screw to the distal end of the shank, and the knife is attached to an inner flexible steel rod, manipulated by a thumb-screw at the proximal end of the instrument. By turning this screw, the knife is drawn out from its concealed position within the bulb, the back of the blade sliding over a firm inclined plane. An index on a dial-plate indicates the amount of projection of the blade, the maximum projection being two millimetres and a half. A small sliding ring on the spiral tube is used to indicate the distance of the stricture from the incisor teeth. I selected the metallic spiral tube for the shank of the instrument, because it combines flexibility with strength. The bulb being conical, the operator can readily perceive when it comes in contact with the stricture, before he projects the blade. In operating, a bulb must be employed which exactly fits the stricture; the depth of the incision will then just equal the distance to which the blade is projected by the action of the screw in the handle.*

The subsequent progress of the case may be given in the following brief extracts from my note-book:

June 15th.—Stricture contracted to 15 F. Introduced œsophagotome with bulb No. 15; passed bulb just beyond the stricture, projected blade two millimetres and a half, and incised the resisting tissue in the posterior median line. The operation was nearly painless, and only a few drops of blood followed the incision. The wound was allowed to remain undisturbed for twenty-four hours, the patient meanwhile being nourished by rectal enemata. These seemed to cause pain in the abdomen, and were therefore discontinued on the day after the operation, the child being permitted to swallow milk, which she did without pain. On the same day dilatation was resumed, and the stricture was found to admit No. 19.

26th.—Daily introduction of elastic bougie since last date has failed to accomplish any further dilatation. Incised stricture on right side to a depth of two millimetres, using bulb No. 19.

29th.—Nothing having been gained by the last operation, the same instrument was introduced, and an incision two millimetres and a half in depth was made obliquely backward and toward the left side. Considerable resistance was offered to the knife, and much soreness followed the operation, rendering dilatation unusually painful. Although a very few drops of blood escaped when the incision was made, the bougie used during the succeeding week was always found stained with blood on being withdrawn.

July 12th.—Dilatation arrested at 23. Arming the œsophagotome with a bulb of this size, I introduced it as before, and made an incision backward and toward the right side, two millimetres in depth. The knife encountered very little resistance, and the operation was followed by slight hæmorrhage, the blood expectorated being about half an ounce.

23d.—Dilatation has reached No. 26, and patient is allowed, for the first time, to take solid food, which she swallows with-

* The instrument is made by Messrs. G. Tiemann & Co.

out difficulty. It may be remarked, incidentally, that no subsequent trouble was experienced in swallowing ordinary food.

August 1st.—Dilatation has not gone beyond No. 27. With bulb of this size made an incision in posterior median line. Depth, two millimetres.

20th.—Dilatation reached 31 on August 12, but, treatment having been suspended for a week, it was ascertained that the stricture had contracted to 27. To-day, using instrument with bulb 27, incised in posterior median line to a depth of two millimetres. I had now determined to make all the incisions that might be required, as far as possible, in the same plane, with the object of gradually and safely effecting complete division of the stricture-tissue, or of rendering it so thin that it could offer no obstacle to dilatation.

October 7th.—Limit of dilatation 34. Since last date treatment was once suspended for eighteen days, when contraction took place from 34 to 26. Made an incision in posterior median line, with bulb 34, projecting the blade two millimetres.

31st.—Dilatation reached 39, beyond which point it was not thought best to carry it.

November 19th.—Patient started for home, being in excellent health, and weighing 62½ pounds, having gained 21½ pounds since treatment was commenced, nine months ago.

In a letter dated January 4, 1884, Dr. Doughty writes that "there is no evidence of a tendency to recontraction, and the function of the œsophagus is as perfect as it was before the injury was inflicted." Bougies are still employed, however, in the hope of obtaining a radical cure. I have neglected to state that, before the child left New York, there were signs of catarrhal inflammation in the neighborhood of the stricture, the bougies, when withdrawn, being stained with a little pus. This symptom has since disappeared.

I am not willing to assert that in the case I have narrated a permanent cure has been effected, but I think it may be affirmed that the treatment pursued has been successful in preserving the child's life and in restoring her to comparative health and comfort. Should dilatation fail to prevent recontraction, I would not hesitate to resort again to internal œsophagotomy.

The limits of this paper forbid any attempt to consider fully the general subject of treatment of cicatricial narrowing of the œsophagus; yet a brief enumeration of the several methods at our disposal may be profitable by helping us to estimate the relative value of the operation now under discussion:

1. Gradual dilatation is usually, and, in my opinion, justly, regarded as the safest and best mode of treatment, whenever it is practicable. It is much to be regretted that this method is not always resorted to, as a preventive measure, or in the incipient stage of the disease, before cicatrization has taken place. It is a fact, however, that the surgeon's aid is rarely sought until the stricture has become narrow and deglutition difficult. I have little doubt that, in many cases, the formation of a stricture might be obviated by the frequent introduction of a full-sized bougie while the healing process is going on; and I believe it should be the rule to commence such treatment within a week or ten days after the injury has been received.

If a stricture is impermeable to instruments, dilatation is, of course, impossible; but, even when bougies can be readily inserted, dilatation is not always successful, as some have maintained, in restoring the distensibility of the con-

tracted parts. This fact is well shown in the case I have described, in which this treatment was faithfully pursued almost daily during the long period of five months. Nor is the introduction of dilating instruments always safe, especially when the stricture is narrow. I am able to recall two cases occurring in my own practice in which an abscess was caused by what I thought at the time to be a cautious use of an elastic bougie. One of these patients recovered, the other died; the fatal event being partially attributed to an accidental perforation of the œsophagus, which led to deep-seated suppuration. A similar accident occurred in the hands of M. Maisonneuve, who perforated the œsophageal wall with a hollow sound; and, believing that the instrument had entered the stomach, injected a quantity of beef-tea into the posterior mediastinum, causing the patient's death on the following day. Finally, treatment by dilatation often requires to be continued indefinitely in order to prevent recontraction; and, as in the case of urethral stricture, persons suffering from stricture of the œsophagus are notoriously prone to neglect themselves, avoiding dilatation until it becomes difficult or impossible.

2. I have already stated, at some length, what I believe to be the indications for performing internal œsophagotomy. The operation has been too warmly advocated by some who have succeeded with it, and too often depreciated by others who lack the experience needed to give weight to their opinions. The number of cases in which the operation has been performed is so small that its value can not be determined by statistics; but the recovery of nine out of twelve patients in whom this procedure has been carried out with beneficial results suffices to shield it from condemnation, and to claim for it serious consideration. The case I have recorded is an example of the class in which the operation may be regarded as proper. When the stricture is narrow, yet permeable, is of slight longitudinal extent, not exceeding, perhaps, a centimetre, and can not be dilated to a size sufficient to permit easy deglutition, I believe the operation of internal œsophagotomy to be the most hopeful expedient at present within our reach. I admit that it can not be performed without some risk, which, indeed, it may be impossible to estimate; but this is warranted by the hopeless character of the disease, and by the results of the alternative operation of gastrostomy. Perhaps the danger attending it may be diminished by proceeding in the cautious manner I have described, so as to avoid injuring any of the important parts which lie outside the œsophagus. The amount of benefit to be derived from the operation will depend on the form and extent of the existing lesion. If the stricture is occasioned by a narrow ring of fibrous tissue, or by a valve-like membrane, a radical cure will probably ensue when this has been divided.* In most cases, however, the operation will prove only an aid to dilatation, rendering this practicable, and perhaps occasionally successful in accomplishing a radical cure. In proportion to the length and induration of the stricture, the utility of internal œsophagotomy will diminish, and in many cases it would be obviously unwise to attempt it.

* *I*vide Case by Roe, "Med. Record," vol. xxii, p. 638.

3. Boeckel* has recently reported two cases of impermeable stricture which he claims to have cured by electrolysis. An œsophageal tube, armed at its distal extremity with a small ball of copper, was introduced down to the stricture, and then connected by means of a wire with the negative pole of a galvanic battery, the plate connected with the positive pole being placed over the eighth rib, a little to the left of the spinal column. In one case, after three applications of from two to five minutes' duration, a bougie (No. 13) was passed through the stricture, which, after the tenth application, readily yielded to dilatation. In the other case, a bougie (No. 6) entered the stricture after a single application, larger bougies passing at every subsequent sitting. I am unable to determine the value of this novel method of treatment, but am inclined to consider as dangerous any such attempt to penetrate a stricture which will not admit a guide.

4. Strictures situated in the region of the neck, which are either impassable or can not be dilated, have been sometimes treated by external œsophagotomy, the operation having usually been undertaken with the view of establishing a fistula through which the patient may be fed by means of a stomach-tube introduced through the fistula and into the stomach. Mackenzie† has collected five cases, in four of which the operation was followed by death at periods varying from twenty-two hours to eight days. The fifth patient (Bryk's)‡ is reported as having been alive at the end of seven weeks; a later account of this patient, however, is given by von Mosengeil,§ who states that the case terminated fatally from pyæmia six months after the operation. In this case the œsophagus was opened above the stricture, which was three centimetres and a half in length, and was situated just below the level of the upper border of the sternum. It was treated by dilatation, and could be passed only by instruments introduced through the fistula; these caused severe pain, frequent hæmorrhage, and finally a deep-seated abscess. In another case (Horsey's||) the œsophagus was likewise opened above the stricture, which was found to be impassable. No encouragement, therefore, is afforded to repeat this operation with the object of establishing a permanent fistula, as there is no certainty that an opening can be made below the seat of obstruction. If the patient is doomed always to be fed through an artificial operation, gastrotomy is the operation which should be selected, as it secures a ready access to the alimentary canal below the stricture, and places the fistula in a situation where it can be easily hidden from view.

But evidence can be brought to show that external œsophagotomy may be of great service by enabling us to deal successfully with strictures that are impermeable to instruments introduced through the mouth. Within the past year Gussenbauer^ has published an account of two cases of deep-seated stricture in which he achieved success

by a method he calls combined œsophagotomy. The first case was that of a woman, twenty-six years old, who suffered from a light stricture caused by swallowing sulphuric acid. The stricture extended from the cricoid cartilage to the bifurcation of the trachea, and, at the time of operation, was impassable to all instruments introduced through the mouth. The œsophagus was laid open by an external incision; and, when the margins of the wound were held apart, the operator passed a probe downward a distance of eight centimetres, where it was arrested, at the point of greatest constriction, opposite the tracheal bifurcation. He finally succeeded in passing through the stricture a probe one millimetre in diameter, and then a very fine-grooved director, upon which, with a narrow-bladed herniotome, he incised the cicatricial tissue in two directions, namely, forward toward the right and forward toward the left side. An elastic catheter, eight millimetres in diameter, was now introduced through the wound and into the stomach, and was retained until the fifth day, for the purpose of increasing the dilatation of the stricture and of injecting fluid food. It was then removed; and, until the fistula closed, three weeks after the operation, the patient was fed by means of the stomach-tube introduced through the mouth. A week later, when she left the hospital, she could swallow solids without difficulty, and could herself readily pass a bougie twelve millimetres in diameter. Neglecting to follow the advice she had received, to continue treatment by dilatation, she returned to the hospital three months subsequently, in the same condition as that first described, so that the operation had to be repeated. The wound in the neck healed at the end of three months, and when the patient was last seen, fourteen months after the second operation, the stricture admitted a bougie twelve millimetres in diameter. During the interval, however, she had suffered considerably in consequence of failure to practice frequent dilatation; and it seemed probable that this treatment would be required indefinitely in order to guard against recontraction.

The second case was that of a child, two years and a half old, who had become greatly reduced in consequence of a stricture due to the action of carbolie acid which had been swallowed two weeks after birth.* Before the operation, a bougie, three millimetres in diameter, was arrested at a point one centimetre below the cricoid cartilage; one, two millimetres in diameter, descended to the level of the manubrium sterni, while no instrument could be made to enter the narrowest constriction, which was near the cardiac orifice. By an operation like the one already described, the strictures were incised, the incisions in the cardiac structure, which lay nine centimetres below the opening in the neck, being two millimetres in depth and six millimetres in length. The external wound closed in thirty-five days; treatment by dilatation was practiced, and, when the child was discharged from the hospital a week afterward, she was able to swallow solid food, and a bougie having a diameter of ten millimetres could be passed into the stomach. After the lapse of a year, when the case was reported, the patient still remained well, dilatation being continued by passing bougies once a week.

^ "Zeitschrift für Heilkunde," Bd. iv, 1863, p. 33.

A third case, in which a similar operation was successfully performed, has just been recorded by Bergmann.* In this instance the stricture, which was caused by the action of oxalic acid, was situated in the neck, at the level of the third tracheal ring. The patient was an adult; and, although before the operation the stricture appeared to be impermeable, it was successfully penetrated after the parts were exposed to view; and the division of a valvular cicatricial fold with a tenotomy knife enabled the operator to pass a full-sized œsophageal bougie into the stomach. The opening in the neck healed at the end of five weeks, and the patient, when exhibited three months after the operation, at a meeting of the Berlin Medical Society held last October, was able to pass easily a full-sized bougie.

5. Gastrostomy, when performed merely with the intention of establishing permanently an artificial opening in the stomach, is at present regarded with considerable favor; but it can never be anything more than a last resort in cases otherwise hopeless. Alsborg's† statistics, which are the most complete I have been able to find, show that gastrostomy has been performed in nineteen cases of cicatricial stricture. Ten of these patients died within the first few days, mainly from peritonitis; four survived, respectively, seven, eight, fifteen, and eighteen months, while five were supposed to be living at the time of the report. Probably these are the cases alluded to by Lefort,‡ who has recently said that five persons were known to be alive at the following periods after operation, namely, four months and a half, eight months, twenty months, two years, and three years. These results justify a resort to the operation in certain cases, and it is reasonable to hope that, with increasing experience, the percentage of mortality attending it may be considerably reduced.

Finally, within the past year, Bergmann* has achieved a brilliant success in the treatment of a deep-seated stricture by a method which is both ingenious and original. Already Schede had proposed, and Trendelenburg had attempted, but in vain, the dilatation of an œsophageal stricture by means of instruments introduced through a gastric fistula previously established. Bergmann's patient was a man, forty-four years of age, who had an impassable stricture, forty centimetres from the incisor teeth, due to the action of caustic potash. Gastrostomy was performed on January 29, 1883, and recovery took place without accident. But it was found impossible to prevent a constant escape of the contents of the stomach; and the patient's condition seems to have been very miserable. It was therefore determined to attempt the removal of the stricture. After several trials, the œsophagus was successfully explored by introducing a sound through the mouth while the forefinger was pushed upward through the cardiac orifice; a membranous septum was then discovered, separating the sound from the finger. This was too thick and firm to allow safe and easy perforation by the sound, while the close proximity of the heart and the descending aorta for-

bade an attempt to divide it with a knife. The obstructing membrane was at last safely perforated by the compressing action of a metal clamp, the blades of which were passed through the cardiac orifice to the seat of stricture and made to grasp the end of the sound, this being pressed against the septum so as bring it between the jaws of the clamp. Perforation having been accomplished, the opening was dilated at first with pieces of compressed sponge, and afterward with sounds, until it admitted a bougie one inch in diameter. On May 21st the artificial opening in the stomach was closed by a plastic operation, the function of deglutition having been completely restored. The patient, when exhibited on October 10th, was in excellent health, and was able to introduce a full-sized sound into the stomach. Meanwhile, treatment by dilatation was being continued.

On reviewing the whole subject, we may conclude that certain forms of œsophageal stricture, which have heretofore proved unmanageable, are no longer beyond the reach of surgical art; and that, in some of these, the internal œsophagotomy is capable, not only of saving life, but also of re-establishing the function of deglutition, so essential to its enjoyment.

ELECTRIZATION OF THE SYMPATHETIC AND PNEUMOGASTRIC NERVES,

WITH SIMULTANEOUS

BILATERAL COMPRESSION OF THE CAROTIDS.

By J. LEONARD CORNING, M. D.,
NEW YORK.

ONE of the most favorable localities for *directly* influencing the functions of the brain is situated in the neck. Owing to the contiguity of important anatomical features in the cervical region, we are enabled, by appropriate means, to lay hold simultaneously upon three great physiological principles, and to appropriate the same to the ends of rational therapy.

At a point situated between the angle of the lower jaw and the hyoid bone, on the one hand, and between the internal border of the sterno-cleido-mastoid muscle and the continuation of the tracheal line, on the other, are situated: 1. The internal carotid; 2, the pneumogastric nerve; 3, the sympathetic nerve. Besides these important structures, we have the jugular veins, adjacent subsidiary nerve-stems, etc.

First Proposition.—The ramifications of the internal carotids afford the principal blood-supply of the cortical areas. If that blood-supply be artificially varied, by compression applied to the arterial stem, a commensurate modification of the functions of the higher centers ensues. The extensity and intensity of cortical function are, to be brief, in a certain sense dependent upon the degree of sanguineous irrigation.

The evidence in favor of this proposition is overwhelming, and has been cited by me so often during the past three years that I shall abstain from further repetition of what must now be accepted as an axiom of physiology.

Second Proposition.—The pneumogastric, so far as its effect upon the heart is concerned, belongs in the category of the so-called "regulating" nerves,

* "Deutsche med. Wochenschrift," October 24, 1883.

† Langenbeck's "Archiv," vol. xxviii, p. 75.

‡ "Gazette des hôpitaux," 1883, p. 714.

* "Deutsche med. Wochenschrift," October 24, 1883.

When the pneumogastric is excited either by mechanical means (pressure), chemically, or electrically, the frequency of the heart's action is diminished. Where the excitation is very severe, it is possible to cause cessation of the latter (Ed. Weber).

After the commencement of the excitation, a short time elapses before the retarding influence upon the cardiac action begins ("Latent Stage" of Donders and Prahl).

Third Proposition.—The sympathetic nerve has a direct modifying influence upon the circulation, metamorphosis (nutrition), and calorification of the organs and histological elements to which it is distributed.

When the cervical sympathetic is excited by the galvanic current, for example, the following phenomena are observed: 1. Dilatation of the pupil and protrusion of the eyeball; 2. Contraction of the vessels and diminution of

physiology, it is evident that, if we could diminish the caliber of the two arteries which supply by far the greater amount of blood to the brain, and at one and the same time excite the pneumogastric and sympathetic nerves, we should be able to exert a very complete physiological control over the metamorphosis of the organ. With the object of obtaining this threefold end, I have devised certain electrical attachments to an instrument, previously designed by me for simple, temporary compression of the carotids.

As this instrument may be unknown to some, I will give a brief description of its construction and method of application.

The chief features of this appliance are two curved metallic armatures, to each of the extremities of which is attached a small sponge electrode. These sponge electrodes are insulated by means of hard rubber plates from the metal armatures, to which they are secured by a simple slide. Moreover, they can be detached when it is desired to employ simple compression, without electrization of the nerves. To each of the electrodes is attached a small conducting cord. These conducting cords unite in one common stem, so that the polarity of both electrodes is the same. The other end of the stem is secured to one of the poles of a galvanic or faradaic battery, as required.

It is possible by means of a screw, provided with a detachable key, to place the electrodes at any desired angle. The object of this device is to enable the operator to exercise pressure upon the carotids in an oblique direction, so as to press the latter away from the jugular vein, and in the direction of the spinal column. By this means it is possible to reduce venous compression to a minimum, except where undue pressure is employed.

FIG. 1.—*a a'*, insulated sponge electrodes in connection with the bifurcated conducting wire *b*; *c*, milled wheel, the rotation of which causes the screw *d* to act upon the armatures *c c'*, thus enabling the operator to expand or approximate the latter at will.

temperature in the corresponding half of the face and brain (*Vide* the experiments of Nothnagel, Claude Bernard, Brown-Séquard, and others).

Granting that the preceding propositions embody sound

FIG. 2.—*A*, differential calorimeter, connected with the thermo-electric piles *d d'* by means of the conducting wires *e e'*. *B*, galvanic battery connected with the electro-compressor *C* by means of the bifurcated conducting wire *f*. The electrode at the extremity of the other conducting wire is placed on the neck.

The disengaged extremities of the curved armatures are attached to a handle. This handle is pierced by an Archimedean screw so arranged that, by simply rotating a milled wheel, the armatures can be extended or approximated at

will. An exceedingly fine adjustment is thus rendered possible.

The method of employing the instrument just described is exceedingly simple. The patient, if in bed, is placed in a horizontal and semi-dorsal position, with the head supported by a cushion beneath the neck, in such a manner as to allow the former to fall slightly backward, while the cervical vertebrae are protruded anteriorly. The operator then takes his place by the bedside, his left side being turned toward the patient. Then, having with the index-finger and thumb ascertained by careful exploration the exact position of the carotids, he proceeds, after accurately adjusting the armatures, to apply the instrument in such wise that the electrodes will press the arteries away from the pneumogastric nerve and jugular vein in the direction of the spinal column. In applying the instrument, it should be held in the right hand, the handle of the same forming a perpendicular to the arteries. By pressing the left hand firmly against the posterior portion of the neck, the operator is enabled to execute any counter-pressure which may be required, and at the same time to contribute to the support of the head in the desired position. Compression should, however, never be carried so far as to cause entire closure of the lumina of both arteries; such a procedure may cause convulsions, as the anastomotic facilities at the circle of Willis are usually unequal to these unwonted circulatory exigencies. This contingency is, however, not liable to arise, as the degree of pulsation in the temporal arteries affords reliable information as to the extent of the circulatory obstruction.

When the instrument has been properly adjusted, an assistant applies the disengaged electrode (usually the positive) over the posterior aspect of the cervical vertebrae.

All being in readiness, the strength of the battery is gradually increased.

It is impossible to determine in advance how many cells may be required, as this will depend greatly upon the strength of the battery, the thickness of the cervical adipose tissue, and the degree of compression employed. The greater the amount of compression the less the strength of the current should be, and *vice versa*.

Care should be exercised to avoid dizziness or syncope, and the strength of the current and degree of pressure should at all times be regulated with the utmost nicety. Sudden variations in either of these factors are to be carefully avoided.

By reference to the physiological proposition at the beginning of this article it will be seen that we accomplish simultaneously a threefold end by this method of treatment, namely: (1) Diminution of the amount and pressure of the cortical blood-stream; (2) contraction of the cerebral capillaries; and (3) retardation of the heart's action (*when currents of considerable strength are employed*).

Besides these results, it is extremely probable, judging from experimental researches, that a *direct* limitation of the processes of intra-cellular activity is also attained.

Theoretically, a more perfect method of limiting cerebral metamorphosis can hardly be imagined. The advantages of this mode of treatment are, moreover, demonstrated

in practice, particularly where we have to deal with insufficiency of the vaso-motor mechanism.

Thus, in congestive headache (angio-paralytic form of migraine) its effects are positively magical. Such cases may frequently be cured in the space of a few moments by resort to this mode of treatment. I know of no remedy at all comparable with this.

I have great hopes also that this means of treatment may prove of value in epilepsy, although my experience with it in this connection is still too limited to express a positive opinion as to its ultimate value as a therapeutic measure in this disease.

On *a priori* grounds, I am inclined to anticipate good results from its employment in the first stages of general paralysis of the insane. I am at present about to engage in some researches as to its applicability in this connection.

As to the current to be employed, my experience thus far leads me to give the preference to the galvanic. Sometimes the interrupted galvanic current may be employed, but under such circumstances the current should not be too strong.

Besides the more obvious physiological effects already referred to, I have noticed the following phenomena in connection with the procedure just described: 1. Dilatation of the pupil. 2. Drowsiness. 3. Dizziness (where too great pressure or excessively strong currents are employed). 4. Drooping of the eyelids. 5. Retardation of the heart's action (where strong currents are used). 6. Pallor about the lips and upper portion of the face. 7. Muscular weakness, as proved by the dynamometer; the subject, if standing, complains of weakness in the knees. 8. If the compression and strength of the current be great, syncope may be produced. 9. Diminution of the temperature over the parietal bones. Lombard's thermo-electric differential calorimeter shows a very considerable difference between the peripheral temperature and that of the head. 10. Very interesting is the observation that the primary stage of excitement incident to etherization is cut short by resort to this method, and the amount of the anæsthetic required proportionately reduced.

The location of the point in the neck which I have thus far adopted as being the best suited to this method of treatment is described at the beginning of this article.

The sudden cardiac depression, so much feared by some of the opponents of galvanization of the sympathetic, is easily avoided by proper caution as to the strength of the current.

One of the great advantages of this method of treatment consists in the possibility which it affords of employing comparatively weak currents, as well as very moderate arterial pressure.

From my own observations, I can not help believing that this method of treatment represents a substantial advance in electro-therapeutics.

Galvanization of the sympathetic is far more effectual when thus employed than when used without simultaneous compression of the arterial stems. The reason for this is plain. Owing to the reduced arterial tension in the smaller vessels, consequent upon compression of the main trunks

(carotids), it is far easier for the muscular coats of the former to contract, as the resistance to be overcome is considerably diminished.

It is hardly necessary to draw attention to the solid physiological basis upon which this method of treatment is based.

When, however, as in this instance, both physiology and empiricism coincide, we have a strong case.

A CONTRIBUTION TO THE TREATMENT OF FRACTURE OF THE SURGICAL NECK OF THE HUMERUS.

By W. T. OPPENHEIMER, M. D.,
HOUSE SURGEON TO BELLEVUE HOSPITAL.

O. G., a strong, healthy man, aged thirty-five, was admitted to Bellevue Hospital on the third of November, 1883. When brought in he was in a state of shock, but rallied promptly under stimulation, and gave the following history:

That afternoon, while standing on a scaffold erected near the ceiling of the third floor of a building, for the purpose of placing a large iron wheel upon a shaft, the weight of the wheel caused the structure to give way, and he fell about forty feet, striking his arm across a wooden railing which surrounded a hatchway in one of the floors below.

An examination revealed the presence of a lacerated wound about four inches in length, occupying the central and upper portion of the axilla on the right side, communicating with the shoulder joint. There was a compound and comminuted fracture of the surgical neck of the humerus, and the short head of the biceps was torn across.

There was a general oozing of blood from the wound, but no large vessel had been injured. Two ribs were also found to be fractured on the same side. The axilla was shaved, and the wound thoroughly washed out with a solution of bichloride of mercury, one part to two thousand.

Two large rubber drainage-tubes were then inserted into the bottom of the wound through two counter-openings, one on the side of the chest, and the other on the inner side of the arm, below the original wound.

The original wound was then closed with a continuous suture of carbolyzed catgut, and a thorough antiseptic dressing applied.

A strong plaster-of-Paris jacket, reaching from the hip-bones to within three inches of the axilla, was then applied to the trunk, while one end of three stout bands of sheet-iron was incorporated into its different layers during the application. The first of these bands was placed at the upper margin of the jacket, the second in the middle, and the third at its lower border.

The fracture was then reduced, the arm placed in a comfortable position, and a plaster dressing applied so as to completely encircle the arm from the wrist to a point opposite the upper band of sheet-iron projecting from the side of the body-splint. Above this point the arm-splint was arranged in the form of a gutter, so as completely to cover the outer aspect and top of the shoulder.

The projecting ends of the bands of sheet-iron were now incorporated in the arm-splint by a few additional turns of the plaster roller in the following manner:

The upper one was bent around the front of the arm three inches below the axilla, so as to hold the arm about three inches from the body at that point.

The middle one passed around the back side of the elbow joint, so as to keep the elbow about five inches from the trunk,

while the lower one passed under the wrist in such a way as to keep it about two inches from the anterior superior spinous process of the ilium, and allow the hand to rest upon the groin (see cut). As soon as the dressing had hardened suffi-

ciently, the edges of the plaster cap covering the shoulder were perforated with a number of openings, into which broad bands of muslin were fastened, and these, carried through the opposite axilla and tied, gave additional security to this part of the dressing.

The patient could now change his position in bed at will, without assistance, without pain, and without in any degree disturbing the fracture.

The wound being at the apex of a triangle having the body and the inner aspect of the arm for its sides, and the upper iron band for its base, the dressings could be changed at any time without displacing the fracture.

The first dressing was changed on the seventh day from the injury.

The original wound had healed throughout by first intention, and, as there had been no discharge from the drainage-tubes, they were removed.

The second dressing remained on until the patient was able to get out of bed, at the end of the third week.

The whole splint was removed at the end of the fifth week, and the shoulder supported with a simple spica bandage and sling.

The fracture was found to be firmly united without deformity, and the motions of the joint were in every way satisfactory.

I attribute the success of the case entirely to the complete immobility of the parts and the absolute rest obtained by the peculiar arrangement of the dressing.

I believe that a similar dressing will be found to be of great utility, not only in the management of fractures about the upper articular extremity of the humerus, but also for those at the elbow joint, together with some of the more difficult fractures of the clavicle, especially where the patient is willing to bear the annoyance of a somewhat heavy apparatus for the sake of avoiding the deformity which so often follows such injuries.

COCA.

By H. D. HICKS, M. D.,

BOSTON.

THOUGH several years have passed since coca has been introduced into medicine, I find, upon inquiry among my fellow-physicians, that its use is extremely limited. Many druggists do not keep it in stock, saying that they have no call for it. Some have obtained it for me, the only one prescribing it among the physicians sending recipes to their establishments, and I have found a few that confessed ignorance as to both its existence and uses.

I have used it both personally and in my practice, and find it of great service in the following conditions:

To prevent and relieve fatigue.

In those cases of backache accompanied by high-colored urine with excessive amounts of urates and uric acid.

In short breathing dependent upon weakness of the muscles of respiration.

Palpitation of the heart, without valvular lesion, due to dilatation or to weakness of the heart muscle.

It renews the vigor of the intellect, and relieves mental exhaustion, rendering the flow of thought more easy and the reasoning power more vigorous.

It dissipates "the blues," leaving the mind calm. By its use the depression following an indulgence in alcoholic liquors is relieved, and it invigorates the exhausted sexual function due to excessive venery.

It destroys the craving for alcohol, and, in small doses, is useful in sick headache and headache resulting from over-exertion. Its habitual use as a part of the daily diet conduces to mental clearness and activity, freedom from fatigue, and sound sleep.

I have to relate three instances in which its action seems to me remarkable:

CASE I.—The first case is my own. When my attention was first called to the article, great stress was laid upon its power of preventing and relieving fatigue. At that time I was accustomed to take long walks about the country, and always came home quite fatigued. I procured some of the coca leaves and determined to give it a thorough trial. One fine autumn afternoon I started out and walked to a town eight or ten miles distant, and, without resting, began the homeward journey, at about one third the distance of which I became as thoroughly exhausted as I ever remember to have been in my life. Literally, I was unable to go farther, my back and loins and the muscles of my legs being lame and painful. I had with me about one half or three quarters of an ounce of coca leaves, which I proceeded to chew and swallow. In less than twenty minutes all fatigue was gone, the pain in my back and legs had fled, and I started homeward at a swinging gait, arriving there as fresh as

when I started. Ordinarily such a walk would have laid me up for two days, but the next morning saw me perfectly well and ready for another tramp. I have used it since on long tramps, with the effect of not becoming fatigued during even the longest.

CASE II.—A lady friend and patient is occupied during the months of August and September in the business of preserving the various fruits and vegetables for market. Hitherto at the end of the season she has been utterly worn out by her exertions, and an attack of illness has been the general result. During the last summer (1888), by my advice she used the fluid extract of coca whenever necessary to relieve her fatigue, and, though working harder than ever before, on account of an increased business, has by its use been enabled to pass the season without losing an appreciable amount of flesh, and without great fatigue. Previously she had been troubled with intolerable pain in the muscles of the arms and hands, which prevented sleep at night. This summer has seen a total abolition of this annoying symptom, and the nights have been passed in sound, refreshing sleep.

CASE III.—A physician, about sixty years of age, employed in clerical work, has been troubled since youth with a dilated heart without valvular lesion (the description of his symptoms is his own). The least hurry, exertion, or mental worry resulted in palpitation and dyspnea. In Boston at various periods of the year we have very damp, oppressive weather, whether warm or cool, when the air is saturated with moisture. On such days even a well man is uncomfortable, but the gentleman above mentioned dreaded these days most of all, on account of the extreme distress arising from short breath, palpitation, and also faintness. His nights for the greater part of the time were almost sleepless, three or four hours at the utmost being his daily allowance of slumber. On account of this insomnia, the hours when others slept were devoted to labor, thus aggravating the trouble.

The only thing that would alleviate the oppression was whiskey. Digitalis, even in the smallest doses, so excited the irritable heart that its action became so violent that respiration was seriously compromised. Hyoscyamus, too, was of no avail. Several times he has fallen insensible, and once or twice has been revived only with great difficulty and prolonged exertions. At the periods of attack of palpitation and dyspnea the stomach was unable to digest food.

On the whole, his condition was serious, and, though he was able to attend to his work, he expected at any moment to be taken away.

About two months since I recommended him to take the coca, and soon after he obtained both the leaves and the fluid extract. After taking it for a few days he told me, on a close, damp day, such as formerly caused him the greatest suffering, "I don't know that I have a heart." Since that time, though we have had bad weather, he tells me that he has not experienced the least trouble. From being an anxious, quiet man, he has become cheerful and companionable. His appetite has improved and he has gained flesh. He has no need for stimulants, and the craving for alcohol has left him altogether. Instead of passing the greater portion of the night in work, he spends it in sleep. To illustrate this: One night he had worked until about twelve o'clock, and thought to lie down upon the lounge, rest a few minutes, and then resume his occupation. He fell asleep, and woke up at six o'clock in the morning, the first time he had slept so long at one time for years.

I do not doubt but many of your readers can relate parallel cases. I am using it in all cases in which the balance between nourishment and waste is not maintained, and find it a valuable assistance. In regard to the dose, I think

that the one generally given on the bottles—viz., 3 j-iv—is too much. I find just as good effects from 3 ss for an adult.

Book Notices.

The Mineral Springs of the United States and Canada, with Analyses and Notes on the Prominent Spas of Europe, and a List of Seaside Resorts. By GEORGE E. WALTON, M. D., Member of the Société Française d'Hygiène, Paris; ex-President of the Academy of Medicine, Cincinnati, etc. Third Edition, Revised and much Enlarged. New York: D. Appleton & Co., 1883. Pp. xvi-468.

There is little to criticise in a book which simply professes to be a descriptive catalogue of the mineral springs of America. We can only say that Dr. Walton's book appears to us to be a very satisfactory compendium of everything relating to the different springs, including their constitution, their properties, and the means of reaching them. The preliminary matter, comprising about one third of the book, and giving various details, historical, geological, chemical, and therapeutical, in regard to springs and baths in general, is entertaining and well worth reading. It is satisfactory to note that the author has not fallen into the error, so common among writers on special subjects, of making his subject a hobby, and of vaunting mineral springs as a cure-all which would render medicine unnecessary.

A Compend of Materia Medica and Therapeutics, with especial reference to the Physiological Actions of Drugs. For the use of Medical, Dental, and Pharmaceutical Students and Practitioners. Based on the Sixth Decennial Revision of the U. S. Pharmacopœia, and including many Unofficial Remedies. By SAMUEL O. L. POTTER, M. A., M. D., Acting Assistant Surgeon, U. S. Army, etc. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. 141. [Quiz Compend, No. 6. Price, \$1.]

This little book contains much that is good. It seems to be a safe book, and the questions are very suggestive. There is the same objection to it, however, that there is to all compends—students, for whom they are intended, are apt to depend too much on the information they obtain from them and to seek no further; still this one is one of the best which have come to our notice. We notice a very glaring error under the therapeutics of quinine: Ten grains of quinine and a half-grain of morphine are recommended for the abortion of acute catarrh.

A Pharmacopœia of Selected Remedies, with Therapeutic Annotations, Notes on Alimentation in Disease, Air, Massage, Electricity, and other Supplementary Remedial Agents, and a Clinical Index; arranged as a Hand-Book for Prescribers. By EDMUND A. KIEBY, M. D., M. R. C. S. E., late Physician to the City Dispensary. Sixth edition, enlarged and revised. Philadelphia: P. Blakiston, Son & Co., 1883. 4to, pp. 134. [Price, \$2.25.]

THE *raison d'être* of this book is not very obvious. There are numerous works already—pharmacopœias, dispensatories, formularies, and what not—which cover all that this one does, and more too. The book consists simply of a handsomely printed and handsomely bound formulary, the prescriptions of which are arranged in a pharmaceutical order; i. e., according to the special kind of preparation—pill, powder, or granule—ordered. In addition, there are some details upon the subject

of diet, and a few hints (for they are nothing more) upon other matters, such as electricity and massage. The whole is well illustrated with pictures of suppositories, croup-kettles, etc.

On the whole, we are sorry to see so much good typographical work expended to so little account. The prescriptions themselves are doubtless good enough, being derived from the formularies of the London hospitals; and, if they were printed in a condensed form and in an inexpensive way, they might serve a useful purpose, which in the form before us they seem not likely to fulfill.

BOOKS AND PAMPHLETS RECEIVED.

Report of the Commissioner of Health on Illuminating Gas, made to the Committee on Lamps and Gas of the Common Council of the City of Brooklyn, July 3, 1883. Pp. 409-ii.

School Hygiene. By Charles J. Lundy, M. D., etc., Detroit, On Life and its Lessons; being the Inaugural Address delivered to the Bristol Medico-Chirurgical Society, in the Session 1882-'83. By James George Davey, M. D., etc.

The Hip and its Diseases. By V. P. Gibney, M. D., Professor of Orthopædic Surgery in the New York Polyclinic, etc. New York: Bermingham & Co., 1884. Pp. 412.

A Manual of Medical Jurisprudence, with special reference to Diseases and Injuries of the Nervous System. By Allan McLane Hamilton, M. D., Consulting Physician to the Insane Asylums of New York City, etc. With Illustrations. New York: Bermingham & Co., 1883. Pp. 386.

Excessive Venery, Masturbation, and Continence: the Ætiology, Pathology, and Treatment of the Diseases resulting from Venereal Excesses, Masturbation, and Continence. By Joseph W. Howe, M. D., etc. New York: Bermingham & Co., 1884. Pp. 299.

Diseases of the Bladder, Prostate Gland, and Urethra. Including a Practical View of Urinary Diseases, Deposits, and Calculi. Illustrated by numerous Wood Engravings. Fifth Edition, revised and much enlarged throughout. By Frederick James Gant, F. R. C. S., etc. New York: Bermingham & Co., 1884. Pp. xiii-616.

A Practical Treatise on Surgical Diagnosis, designed as a Manual for Practitioners and Students in Medicine. By Ambrose L. Ranney, M. D., Professor of Practical Anatomy in the New York Post-Graduate Medical School, etc. Third Edition, thoroughly revised, enlarged, and profusely illustrated. New York: William Wood & Co., 1884. Pp. xx-608.

A System of Oral Surgery: Being a Treatise on the Diseases and Surgery of the Mouth, Jaws, Face, Teeth, and Associate Parts. By James E. Garretson, M. D., D. D. S., Dean of the Philadelphia Dental College, etc. Illustrated with Numerous Steel Plates and Woodcuts. Fourth Edition, thoroughly revised, with additions. Philadelphia: J. B. Lippincott & Co., 1884. Pp. 1,037.

Legal Medicine. By Charles Meymott Tidy, M. B., F. C. S., etc. Vol. III. New York: William Wood & Co., 1884. Pp. xxi-321. [Wood's Library of Standard Medical Authors.] Annual Address delivered before the American Academy of Medicine at New York, October 10, 1883, by Henry O. Marey, A. M., M. D., President of the Academy.

Simulation of Insanity by the Insane. By James G. Kierman, M. D., Chicago. [Reprint from the "Alienist and Neurologist,"]

On Bedside Urine Testing, including Quantitative Albumin and Sugar. By George Oliver, M. D. Lond., M. R. C. P. Second Edition. London: H. K. Lewis, 1884. Pp. 128.

Suggestions regarding the Local Treatment of some of the Commoner Affections of the Ear. By Samuel Theobald, M. D., Baltimore. [Reprint from the "Maryland Medical Journal,"]

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FORSTER, M. D.

NEW YORK, SATURDAY, FEB. 23, 1884.

A PROPOSED NEW PHARMACOPŒIA.

THOUGHTFUL and right-minded men are generally supposed to agree that all government is a necessary evil, never to be amplified save as a necessity; but it seems occasionally as if a portion of the medical profession were straying away from this sound position, and, like the Children of Israel of old, were pining for a king. The latest example of this tendency that has come to our notice is the movement in favor of a new pharmacopœia, in furtherance of which a bill has been introduced into Congress providing for the issue of a new pharmacopœia by the Government. It is argued that the pharmacopœia ought to have the force of law. Now, there is a grain of truth in this broad proposition; but, for all legitimate purposes, any State can give the present pharmacopœia the force of law, and, for that matter, a court can do the same, as was lately exemplified in Massachusetts, where several manufacturing druggists were punished for furnishing pharmacopœical preparations that were not up to the pharmacopœial strength.

It seems to us that a standard strength and a standard purity are all that the Government can legitimately enforce in the matter of drugs, but this is not all that it might assume to do if the pharmacopœia were to be made a legal standard in the full sense of the term. In the case of most preparations, the pharmacopœia lays down detailed processes. To make it incumbent on pharmacists to adhere slavishly to these processes, however good they may be in the present state of the art, could not but act as a clog upon the advancement of pharmacy. Even if this were not the case, we can see no good object to be gained by giving legal force to the pharmacopœia, except in so far as may be necessary to provide against danger to the community from the administration of drugs of greater strength than the prescriber supposes, and to guard against fraud on the part of dealers in the matter of drugs of inferior strength or purity. Further than this there is no occasion to go, and further than this the Government can not go, in our opinion.

It is perfectly competent, of course, for the Government to assume the expense of issuing a pharmacopœia, if that is the point aimed at, but even that would be contrary to the traditions of our Government, and seems to be wholly uncalled for, as the present pharmacopœia is entirely self-supporting. It is only a little more than a year since the revision of 1880 was issued, and we understand that there is already a surplus of money in the hands of the committee, in whom the copyright is vested. But not only has the book met with this material success; it has proved a *succès d'estime*, reflecting the highest credit upon the committee and upon the state of pharmaceutical science in America. Faults it has, beyond question, as we

were not backward in pointing out, in a series of articles we published on it about a year ago, but for the most part they are trifling and not for a moment to be weighed against its great merits. It may be said of the revision of 1880 (what could never before be said of a United States pharmacopœia) that it has commanded the admiration of all competent critics, however critical, both at home and abroad. The present time seems, therefore, very inopportune, for changing the method of constituting the body of men to whom the prosecution of the work of revision is confided. It is extremely doubtful if a committee appointed by the Government would do the work even as well as the committee of 1880 did it. The point is urged, we understand, by the supporters of the bill, that the medical corps of the army, the navy, and the marine-hospital service should be largely, if not wholly, charged with the work; but it should be remembered that the present method of constituting the committee gives a liberal representation to those branches of the public service. All things considered, we must express the hope, therefore, that the profession will show its appreciation of the great amount and the creditable character of the work done for it by the committee of 1880 by declining to sanction this move to supplant the method which has been found to work so well.

VETERINARY MEDICINE IN AMERICA.

WHATEVER we, whose more particular province it is to deal with medicine in its application to the ills of human flesh, may think of the present status of our art, however lofty our aspirations may be for a state of things in which more pure science shall be mingled with it, we can scarcely lose sight of the fact that our colleagues whose work lies among the lower animals have lately given abundant signs of a determination to raise themselves and their art from the position of unmerited degradation, more or less pronounced, in which public opinion has heretofore held them. That they have already accomplished much in this direction may be gathered from the expressions of indignation which were called forth, and not from their ranks alone, when a lawyer in the employ of the Government sought to advance his case by holding one of the witnesses up to ridicule as a "horse-doctor."

The witness alluded to was none other than the founder of the "Journal of Comparative Medicine and Surgery," the perusal of a recent issue of which has suggested these reflections. The journal in question is a quarterly, now in the fifth year of its publication. During the greater part of its career it has been under the editorial control of Dr. W. A. Conklin, the Director of the Central Park Menagerie, and its pages have been the repository of many curious and valuable facts and observations that were the fruit of his labors at the park. With the January number Dr. Billings, of Boston, became connected with the journal as associate editor. Dr. Billings's accession is signalized by a vigorous editorial article entitled "The Scientific Method in Veterinary Education," in which the determination that we have alluded to is plainly manifested. We notice, also, a clever editorial article exposing the fallacy into which a Ger-

man author has fallen in attributing trichiniasis in American hogs to the "hundreds of thousands of Chinamen" employed in the pork-packing establishments of this country—the theory being that rats are frequently trichinous, that Chinamen eat rats, and so on!

When the hero of "The Diary of a Physician," having been called upon to prescribe for a pet monkey, found it difficult to suppress his sense of humiliation, while forced by poverty to obey the summons, he exemplified a feeling that can never exist save as the result of ignoring the value of knowledge of whatever sort and the dignity of the study of any branch of natural science, whether it relates directly to man or to the lowest forms of organisms, or, for that matter, to the inorganic bodies. Far, indeed, from there being any real ground for those who practice only upon the human organism to look down on their veterinary brethren, it might not be altogether to the glory of the former if a comparison were to be drawn between what the two classes have done for the advancement of the common science. When we call to mind how much pathology owes to the veterinarians, and how much of our best contemporary literature still comes from them, we must confess that it is not in the domain of comparative medicine alone that self-criticism is in place. But the state of things we have pictured has not hitherto obtained in this country. Now, however, various circumstances are at work to bring the conditions here into conformity with what is true of the Old World. One element that contributes powerfully to this end is, unquestionably, the attention which the Government has found itself forced to give to the health of domestic animals, and the consequent knowledge that the public has acquired of the intimate relations between man's health and that of his brute companions. But it is very much to the credit of the veterinarians that it can be said that not the least potent of the circumstances to which we refer is their own progressive tendency.

MINOR PARAGRAPHS.

THE YELLOW FEVER AT PENSACOLA.

We have before taken occasion to remark upon the excellent work done by the Naval Medical Society. We would now call attention to a number of papers read, and remarks made, at the November and December meetings of the society, as we find them recorded in the current number of the "Proceedings." Important papers on the subject of yellow fever were read by Dr. J. W. Ross, Dr. William Martin, and Dr. D. M. Guiteras, and Dr. A. A. Hoehling made some timely and spirited remarks, closing with the statement that, if he had added a "drop in the bucket" which should one day wash away the "commercial" ætiology and diagnosis of the disease, he would not have spoken in vain. When fear of the loss of business, he added, caused communities and their physicians to call such a disease as prevailed at Pensacola "malaria," or the "prevailing disease," and, when that failed to arrest the mortality, declare it to be non-contagious, though "infectious," it was time to raise a voice in protest.

THE NEW YORK POLYCLINIC.

We are pleased to learn that the prophecy made in this journal almost a year ago concerning the future of this clinical

school for practitioners of medicine has been fully realized. We said: "Such an amount of clinical material has never heretofore been organized and concentrated for the purpose of teaching general or special clinical medicine to practitioners, and, if the judicious management, harmonious co-operation, and energy which have gained so high a position already for this new undertaking in the direction of higher medical education are continued, the success of the movement will be permanent and complete." The Quarterly Circular Announcement of the Polyclinic gives a list of one hundred and seven physicians who have worked in the various classes as students within the first four months of the present session, making a total of two hundred and sixty-eight within the first fifteen months of the existence of the Polyclinic. The fact that the managers have purchased the commodious building heretofore occupied by them in part shows that they recognize the necessity of providing for still more work in the future. We are informed that during the summer months the changes in the building will be accomplished which will make it a most complete polyclinic school and hospital.

THE INSPECTION OF EXPORTED PORK.

A RUMOR having been received by telegraph to the effect that the French Government is now willing to admit American hog products, on condition that they pass an examination to be made at its own expense, it is said that some gentlemen who assume to speak for the pork trade regard this proposal as unsatisfactory, provided it means a microscopical examination. It seems to us foolish for this objection to be raised, and we trust that it will not be brought forward authoritatively, for it is neither founded in fairness nor calculated to convince foreign nations of our faith in our own position. We must not rest on the fact that trichinous pork is harmless when properly cured or cooked; we must exterminate trichiniasis in our hogs.

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 19, 1884:

DISEASES.	Week ending Feb. 12.		Week ending Feb. 19.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	0	1	0
Typhoid Fever	8	4	21	6
Scarlet Fever	91	15	75	14
Cerebro-spinal meningitis.	13	9	6	6
Measles	62	11	70	11
Diphtheria	47	19	47	20

GLANDERS IN CHICAGO.—It is reported that the State Veterinarian discovered two cases of glanders last week in a large stable where a number of horses and mules were kept. The infected animals were ordered shot, and a rigid quarantine was established to prevent the spread of the disease if possible.

THE FOOT AND MOUTH DISEASE was said last week to be prevailing among the cattle at the quarantine station at Deering, Me., and to have been communicated to cattle in Deering and in the neighboring town of Falmouth. The report has been denied, but it has given rise to much alarm in the vicinity.

COUNTERFEIT TARTAR EMETIC.—The "Progrès médical" states that certain German chemists have put on the market a salt purporting to be tartar emetic, but really consisting of an oxalate of potassium and antimony, and warns its readers of the dangers of using such a salt.

POISONING BY WILD PARSNIP.—A case of poisoning from eating wild parsnip occurred in Danville, Pa., on Friday of last week, when two children died after having eaten the plant. A third child who tasted it was made very sick. In the two fatal cases convulsions occurred, preceded by violent pain.

DEATH FROM AN OVERDOSE OF MORPHINE.—On Wednesday, the 13th inst., Dr. J. W. Sherfy, of Brooklyn, a graduate from the Long Island College Hospital in 1861, died from the effects of morphine which he took to relieve the pain caused by a decayed tooth. He had been suffering from Bright's disease.

ST. ELIZABETH'S HOSPITAL.—It is announced that a building adjoining the hospital has been fitted up under the supervision of Dr. W. G. Wylie for the use of private patients, to which the patients of any physician in good standing may be admitted, under the rules of the hospital, and remain under his charge, if desired. In case the physician is not known at the hospital, application must be made to Dr. Wylie.

A NEW SCHOOL FOR MIDWIVES.—We understand that a bill to incorporate the New York Maternity and School of Midwifery, and to regulate the practice of midwifery in the State of New York, has been laid before the Comitia Minora of the Medical Society of the County of New York, for its consideration previous to its introduction into the Legislature. It is said also that the College of Midwifery already in operation in New York now has a bill for its incorporation before the Legislature.

COMPENSATION TO AN ARMY SURGEON.—Measures have been taken looking to a tardy act of justice in the matter of recompensing Surgeon E. P. Vollum, of the army, for the loss of his personal effects by shipwreck while in the line of duty so long ago as the year 1856. The Senate has voted Dr. Vollum the sum of \$700.

THE ARMY MEDICAL CORPS.—The Senate Committee on Military Affairs has reported a bill creating two new grades of medical officers—assistant surgeons-general, with the rank of colonel, and deputy surgeons-general, with the rank of lieutenant-colonel.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 10, 1884, to February 16, 1884:*

PERIN, GLOVER, Lieutenant-Colonel and Surgeon, Medical Director, is granted one month's leave of absence, with permission to apply at Division Headquarters, Missouri, for an extension of one month. S. O. 16, Department of Dakota, February 9, 1884.

To be assistant surgeons, with the rank of First Lieutenant, to date December 3, 1883:

William D. Dietz, Walter W. R. Fisher, William Stephenson, Adrian S. Polhenus, John L. Phillips, Reuben L. Robertson, William C. Borden, Edgar A. Mearns, Guy L. Edie, William D. Crosby, William L. Kneedler, Charles M. Gandy, Charles S. Black, James E. Pilcher, Alonzo R. Chapin. S. O., A. G. O., Washington, February 11, 1884.

BREWSTER, WILLIAM B., First Lieutenant and Assistant Surgeon. Resignation accepted to date February 7, 1884. S. O., A. G. O., Washington, February 11, 1884.

WILSON, GEORGE F., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Walla Walla, Washington Territory. S. O. 14, Department of the Columbia, February 5, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending February 16, 1884:*

COUES, S. F., Medical Director. Assigned to the Naval Medical Examining Board, Philadelphia, March 3d, as the relief of Medical Director P. J. Horwitz, who retires on that date.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, February 25th:* Medical Society of the County of New York.

Tuesday, February 26th: New York Dermatological Society (private); New York Surgical Society (private); Jersey City Pathological Society (private).

Wednesday, February 27th: New York Pathological Society; American Microscopical Society of the City of New York; Auburn (N. Y.) City Medical Association.

Thursday, February 28th: New York Academy of Medicine (Section in Obstetrics); Harlem Medical Association (private); Brooklyn Pathological Society.

OBITUARY NOTES.

DANIEL C. BURLEIGH, M. D., OF THE RETIRED LIST OF THE NAVY.—Dr. Burleigh died in Dresden, Saxony, on the 10th of January last, in his fiftieth year. He entered the navy as passed assistant surgeon in 1864, and resigned in 1869, when he settled in Franklin, N. H., where he practiced his profession until 1873. In 1874 he re-entered the navy as passed assistant surgeon, and was placed on the retired list a few years after. The last three or four years of his life were spent in Europe.

NOBLE B. PICKETT, M. D., OF GREAT BARRINGTON, MASS.—Dr. Pickett died suddenly on Tuesday, the 5th inst., in his eighty-fourth year. He was born in Sherman, Conn., and was graduated from the Medical Department of Yale College in 1834. He settled in Housatonic, a post village in Great Barrington township, in 1845, where he practiced his profession until compelled to relinquish it, a few years since, by increasing blindness.

DR. JEFFERSON S. HOWARD, OF CLAYVILLE, R. I.—Dr. Howard, a well-known and successful physician, died February 6th, at the age of fifty-one. He was a man of great ability and strong convictions, and had occupied many positions of trust and honor, both in professional and in political life.

DR. ALBERT SMITH, OF NEW ROCHELLE.—Dr. Smith died on Tuesday of this week, at the age of eighty-five. He was a graduate of the College of Physicians and Surgeons, of this city, and was in practice here a number of years ago, but retired when about fifty years old, and has since lived at New Rochelle, where he has devoted himself to various measures for the improvement of the town and its people.

JOHN HUTTON BALFOUR, M. D., F. R. S., OF EDINBURGH, died recently, at the age of seventy-five. He was dean of the medical faculty of the University of Edinburgh.

Letters to the Editor.

THE POST-GRADUATE MEDICAL SCHOOL.

February 14, 1884.

To the Editor of the New York Medical Journal:

SIR: The notice of my resignation as a member of the faculty of the New York Post-Graduate School, and of Dr. Ranney's succeeding me, is entirely incorrect. I am still the professor of the anatomy and physiology of the nervous system at that school, and Dr. Ranney has no connection with my chair of any kind whatsoever. Sincerely yours,

E. C. SPITZKA.

Proceedings of Societies.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of February 7, 1884.

The President, R. A. CLEMMANN, M. D., in the chair.

A YEAR'S WORK IN OVARIOTOMY.—DR. WILLIAM GOODELL read a report of his cases of ovariectomy during the past year. He had had twenty-five cases, with seven deaths. Eleven of the operations were performed in the private rooms of the Hospital of the University of Pennsylvania, with one death; ten were done at the patients' own homes, with five deaths; and four at his private hospital, with one death. He attributed the majority of these deaths to three causes: 1. That he made it a rule never to doom a woman to certain death by refusing to operate on her, however forlorn the hope of her recovery might be, and three of those who died were very ill indeed, at the time of the operation, from septicæmia and purulent cysts. 2. That the women of this country, being unwilling to go to a hospital, either insisted on being tapped, which increased the risks of the radical operation, or else postponed the operation until the tumor had become very large, adhesions had formed, and the health had become greatly undermined. Out of his twenty-five cases he had had but eight without adhesions, and one of these patients died at home after a double ovariectomy, he not having seen her or treated her after the operation. 3. That five of the patients who died had been operated on at their own homes, which were so distant that he was able to see but one of them after the operation, and she did not rally, but died in eight hours, from the shock of the removal of an intra-ligamentous cyst universally adherent. The fatal case at his private hospital was one of pelvic abscess bursting into the bladder. The operation was not a difficult one, although the lower portion of the cyst had to be separated from the two layers of the broad ligament by which it was enveloped. The sole fatal case out of eleven performed at the Hospital of the University was due to hospitalism. This he deemed a good record, for the building was used as a general hospital, with many railroad-accident cases and suppurating wounds. In this hospital he always operated in one of the private rooms, where the patient was kept until all danger was over.

While acknowledging that his results were not so good as those of British ovariologists, he said that, on the other hand, it was to be said in his favor that he never refused to operate on a woman, however slim her chances of recovery. He made this statement because, according to remarks made by Dr. Sutton at the last meeting of the American Gynecological Society, Billoreh was the only one among European ovariologists who "refused to operate upon nothing that deserved the chance of life," and his success amounted to about sixty-five per cent., while one of the most successful of British ovariologists "did not remove very large tumors—viz., those which weighed from sixty to sixty-five pounds, with extensive adhesions," etc.

Out of the twenty-five cases of ovariectomy, there were twelve in which both ovaries were removed. In all these cases the second ovary was positively diseased. Yet, with a larger experience, he (Dr. Goodell) was becoming more and more inclined to remove both ovaries in all cases of malignant degeneration of one ovary; in all women who had passed the climacteric or who were approaching it, and in all cases complicated with fibroid tumor of the womb.

DR. ALBERT H. SMITH felt that Dr. Goodell was hardly right in saying that in England desperate cases were rejected. In his own experience, while in England recently, several cases which

were very desperate, and which would have been generally rejected here, were treated successfully by operation, and the patients were ready for discharge three weeks afterward. It occurred to him that the lower average temperature had much to do with the result. The thermometer was not allowed to rise above 65° F. in the room in which the patient was kept; and in Mr. Lawson Tait's cases it rarely went over 60°, and never up to 65°. Perhaps this had a good effect in preventing hyperpyrexia. The English ovariologists were also very careful as to details, especially in preventing hæmorrhage, and used an immense number of hæmostatic forceps. Ovarian cysts were remarkably common in London. Dr. B. F. DAWSON, of New York, upon invitation by the president, spoke of the English ovariologists, and alluded to what he had himself seen, while on visits to England, as to very desperate cases being treated by operation. His own late experience had been so good that he was inclined to attribute it, as well as the good results of the English operators, to absolute painstaking in the most trifling details, with absolute cleanliness; not simply antiseptics, but the utmost care throughout every step of the operation. Among other things, a very large number of hæmostatic forceps were used, so as to secure each bleeding point the moment that bleeding began. His own last six cases of laparotomy, performed this winter, two of which were very desperate in character, had been successful, and the results he felt were largely due to the avoidance of any preventable hæmorrhage and to great care through all the stages of the operation to prevent blood or fluid from the cyst escaping into the peritoneal cavity. This care was exercised throughout the "toilet of the peritonæum," and he always used a flat sponge, as Sir Spencer Wells did, inside the abdominal walls, upon the intestines, while introducing the closing suture; and the sponge was removed only when it became necessary to do so to twist the last wires. He always used napkins to fold over the edges of the abdominal incision, to prevent the oozing from the edges escaping into the peritoneal cavity or soiling the operator's fingers. He also wrapped the cyst in towels as it was withdrawn from the cavity, to guard against even a trace of fluid soiling the intestines or the wound. He clamped the pedicle temporarily when possible, and placed a napkin under the clamp before dividing and cauterizing it. Every adhesion that showed any risk of bleeding was cauterized as soon as it was separated, even when ligated. Douglas's pouch especially was sponged out until the sponges came away absolutely clean. In a recent very desperate case, one in which Dr. Emmet had expressed his sympathy with him as to its almost certain fatality, the operation occupied two hours and forty minutes, owing to painstaking observance of these details, and, although half of the uterus was removed and adhesions were numerous, calling for many ligatures and frequent use of the cautery, yet convalescence was uncomplicated and speedy.

DR. GOODELL remarked that the quotation in his paper, to which exception had been taken, referred to Mr. Tait. It was taken from a paper read last autumn before the American Gynecological Society by Dr. Sutton, who was with Mr. Tait three months. He (Dr. Goodell) had seen about a dozen ovariectomies in Great Britain; only one was a difficult case, and in that case the patient died. There he had seen patients refused on account of their age, while in this country they were not. Dr. Goodell had operated successfully on patients aged, respectively, sixty, sixty-one, sixty-two, sixty-four, sixty-five, and sixty-seven years, and some one in this city had had a successful case in a patient over eighty-three. Dr. Goodell had once operated upon a patient seventy-six years of age, of a long-lived family. This was before the days of antiseptics, and the patient died. He believed that minute attention to details was the chief element of

success. One important point was to make the abdominal incision sufficiently large to see every adhesion as it was separated, and to ligate or secure every bleeding point immediately. This required a courage which it had taken him years to attain. He always observed Sir Spencer Wells's method of placing a flat sponge beneath the abdominal walls when introducing the closing sutures. He did not like wire, but always used carbolyzed silk sutures, each eighteen inches long. After they had all been placed, the ends were twisted together into one strand on either side and caught in the bite of a pressure-forceps. The lips of the incision were then widely separated and a final search was made for any oozing, leakage, or accumulation of serum. They were then rapidly tied, and the wound was dressed. This final toilet of the peritoneum could not be made when wires were used. He now believed in the use of a drainage-tube, but he had had hard work to bring himself to the point of accepting it, and he still looked upon the tube as a foreign body—a necessary evil. He had once seen death caused in a healthy man by the simple perforation of the peritoneum, without wound of the intestine, by a small stiletto, and this had made him fearful of the effect of the presence of a drainage-tube. But he now considered that the peritoneum in the case of an ovarian cyst had, by thickening and attrition, lost much of its vulnerability, and did not resent slight causes of irritation. He occasionally resorted to the actual cautery at a black heat to stop bleeding from torn adhesions, but he preferred the pressure-forceps, the ligature, or the application of Monsell's solution. He thought there might be some truth in Dr. Smith's idea concerning the effect of the low temperature of the operating-room and of the convalescent-room. He had been struck with the absence of ill results in one operation in London by Dr. Bantock, of which he had been a spectator. The day was cold, damp, and foggy, and the operating-room was chilly, the windows being open; but the patient promptly recovered. In one case of his own, in which the extreme emaciation and prostration of the patient forbade postponement, the operation was done in severe winter weather; the steam pipes at the hospital had been frozen overnight, and, although they had been thawed out, the temperature of the operating-room was only 54°. In this case the cyst had contained colloid matter, and had burst spontaneously; all that could possibly be removed was scooped, sponged, and washed out. Much remained behind, yet the patient recovered, and afterward became quite fat. This operation was performed three years ago; both ovaries were removed, but another tumor could now be discerned in the abdomen. The patient being fat and also very sensitive, it was not possible to determine its character accurately, but he hoped it was a pedunculated fibroid of the uterus, and not a malignant tumor.

Dr. DAWSON requested Dr. Goodell to give his opinion respecting the management of the drainage-tube, and of the importance of the spray.

Dr. GOODELL, when operating in private houses, had begun to dispense with the spray. Carbolic-acid spray poisoned some patients, and he, being afraid of it, only used it when he did not consider it safe to omit it, as, for instance, in a general hospital, or when there were many spectators present. Year before last he lost one patient from its use. She had contracted kidneys. Only last week, in an operation in the Hospital of the University, the patient was profoundly affected by it, and was with difficulty restored by means of digitalis, stimulants, etc. When he omitted the spray, he used the drainage-tube more frequently. If he found in Douglas's pouch, after the sutures had been placed and the sponges removed, two or three drachms of bloody serum, and the source of this oozing could not be found, he inserted a drainage-tube; and he also used it in all cases in which there

had been peritonitis or when septic symptoms were present from a purulent cyst. Over the mouth of the tube he sprang a piece of rubber sheeting, which was folded over a sponge squeezed out of a five-per-cent. solution of carbolic acid. The sponge was examined and squeezed out every few hours, and the tube moved slightly to clear the openings and allow any accumulation of serum to escape. As soon as a moderate amount of serum escaped without any tinge of blood, the tube was removed. This generally happened within forty-eight hours, but in one case it was necessary to allow it to remain five days. He never irrigated the abdominal cavity, but he sometimes introduced the long nozzle of a hard-rubber syringe into the tube and drew out any serum that might have accumulated. When he operated in the country, and left the patient in the hands of the family physician, he tried to avoid the use of the drainage-tube as much as possible.

Dr. DAWSON had given some attention to the question of the drainage-tube. In New York two deaths had lately happened after ovariectomies, and in each case the surgeon had ascribed the fatal termination to the too early removal of the tube. Soon after these unfortunate cases he had operated and had been obliged to use the drainage-tube; on the second and third days after the operation the serum exuding from the tube was bloody. On the fourth day it was pure serum. The patient was doing well, and Dr. Dawson concluded to leave well-enough alone, and, with the result in the two other cases before him, allowed the tube to remain. He used a wire with a pledget of absorbent cotton attached to the extremity, to soak out the accumulated serum, and continued to use fresh pieces until they came away clean. The tube was evidently being walled in by a deposit of lymph around it. On the sixth day, after finding very little serum, the last pledget of cotton brought away a little yellow spot that might have been either lymph or pus. That night he discovered another trace of the same appearance, and the microscope showed it to be pus. The next day the discharge was fetid. A saltspoonful of iodoform was put into the tube every time it was cleaned, and on the tenth day it was removed and a roll of absorbent cotton saturated with iodoform was put in its place. This was replaced in a few hours with another, until all signs of pus ceased. The opening closed in forty-eight hours. The patient recovered. He would like to ask if Dr. Goodell had ever regretted removing a drainage-tube too early? Was a drainage-tube more of a foreign body on the third or fourth day than it was on the first?

Dr. W. H. PARISH had recently performed abdominal section for the removal of a fibroma of the uterus. In this case he used a drainage-tube, although he was not able to pass it down into Douglas's pouch. On the third day he noticed that the serum escaping from the tube was cloudy, and had a slight odor. On the fourth day the odor was quite objectionable, and, as the tube had evidently become separated from the abdominal cavity by the formation of a canal of lymph around it, resembling in appearance diphtheritic membrane, he decided to withdraw the tube. He washed out the canal with a two-per-cent. solution of carbolic acid. The canal soon closed, and there was no return of the offensive odor.

Dr. GOODELL could not recall the loss of a patient after the removal of a drainage-tube. He had had, however, a number of deaths while the tube was still in position, but that meant simply that the cases were complicated and difficult ones. Was not the tube itself the cause of the pus in Dr. Dawson's case? Air containing germs was, of course, admitted into the tube in the cleaning-out process, and these germs would cause decomposition of the lymph. Might not also the tube, acting as an irritating foreign body, cause pus? He introduced a stitch in such a manner, beyond the drainage-tube, as to make tension

of the skin around the tube, and this closed the opening as soon as the tube was withdrawn. He had occasionally followed the removal of the glass tube by the introduction of a rubber one of smaller caliber, but he had discontinued this practice, believing the glass tube to be the least irritating.

ABDOMINAL SECTION.—Dr. W. H. BAKER reported a case for Dr. Walter F. Atlee. Mrs. E. C., of Erie, Pa., was brought to this city by Dr. Edward Cranch. She was forty-five years of age, married, but had had no children. Her menses were regular and very abundant. She was a stout woman in excellent health. Four years ago she first noticed a tumor in the center of the abdomen. Dr. Cranch reported that the probe entered the womb the normal distance only. A multilocular cyst with thick walls and very glutinous liquid, or a fibroid tumor of the uterus, was diagnosed. The sense of fluctuation was not distinct. February 4th, after the usual preparation, the operator cut down, found a solid tumor, opened it, took out as much as possible of the contents, and got out the envelopes; the incision was about five inches in length. The tumor grew from the fundus of the uterus. It was transfixed, tied, and dropped. The patient never rallied after the operation, and died on the 6th, of shock. There was no hæmorrhage. The operation was all over in twenty-five minutes.

Dr. R. P. HARRIS saw the patient prior to and assisted in the operation. The lady had an appearance of health, was quite robust, and there was nothing in the contour or expression of her face indicative of ovarian cystoma. In a conversation with her sister and the family physician, he learned that the diseased growth was first noticed by this sister, who remarked upon the central prominence of the abdomen of the patient, who was at the time lying on her back on the floor engaged in playing with a little child. When the attention of the patient was directed to the fact that her abdomen presented a central elevation, even when flat upon her back, she readily detected the existence of something abnormal. Dr. Harris remarked to the physician that the history of the case indicated the existence of a tumor at the fundus uteri. When the morbid growth was exposed it did not present the appearance of an ovarian cyst; neither did percussion indicate the presence of fluid prior to incising the abdomen, except by a surface wave. There was no wave transmitted from hand to hand. The surface wave was found due to some ascitic fluid. As no fluid escaped by tapping, the tumor was opened and its contents were torn away in pieces, so as to reduce it sufficiently, when it was drawn through the wound, ligated at its union with the fundus uteri, and cut away. During the shelling process a considerable loss of blood took place, and the appearance of the patient was that of great prostration. The tumor had no pedicle, being sessile in its attachment to the uterus.

W. H. H. GITHENS, M. D., *Secretary.*

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of January 9, 1884.

GEORGE F. SHRADY, M. D., *President, in the chair.*

TUBERCULOSIS OF THE TESTES.—Dr. A. G. GERSTER presented the testes of three different patients which he had recently removed for acute tuberculosis. The first specimen was from a laborer, thirty-eight years old, who was recognized to have a hydrocele, but whether simple or dependent upon disease of the testicle was not at first determined. There was no known cause for the condition; he denied venereal disease. Volkmann's operation for hydrocele was successfully performed, the wound healing in a perfectly normal manner; but, five weeks after his dismissal from the hospital, the patient returned, saying that he had passed a bad night, had had a chill, and had begun to lose

flesh and strength. The testicle was then extirpated, and was found to show central tuberculosis, the hard, characteristic tubercular mass not yet having begun to break down. The second specimen showed a slightly more advanced stage of the disease, and was from a man thirty-one years of age, who had suffered acute orchitis and epididymitis of traumatic origin. Six or eight weeks after the injury the testicle was painful, swollen, and hard, the swelling extending up the cord some distance. The patient suffered chilliness and sweating, and presented a condition demanding removal of the testicle, which was done. The chief interest of the specimen related to the condition of the tunica vaginalis, which, instead of being smooth and hard, resembled very much the synovial membrane in cases of tuberculosis of the joints. There was incipient breaking down of the tuberculous deposit centrally. In the third case there had been chills, emaciation, loss of appetite, and swelling and pain of the testicle, and, on removal, the organ was found to consist almost entirely of broken-down tissue; the tunica vaginalis had become obliterated. Dr. Gerster remarked that the diagnosis could be made much earlier in these cases than was formerly done, and lead to proper treatment in the way of extirpation, whereas it used to be the practice to let the condition remain until a fistulous opening formed in the scrotum and the case reached the state falsely called hernia testis. In the discussion which followed, Dr. Gerster said that there had been no physical signs of tuberculosis in any of the other organs of the body. The other general symptoms—chills, sweats, etc.—disappeared on removal of the diseased testicles.

GENERAL MILIARY TUBERCULOSIS.—Dr. FERGUSON presented specimens showing miliary tuberculosis of the kidneys, liver, and lungs, from a man, thirty-five years of age, who was admitted to the hospital on the 19th of December, 1883. Six months previous to admission he suffered from general pains over the body, dyspnea on exertion, and at times from hæmorrhage from some part of the respiratory tract. Cough developed, but did not become continuous until a month before admission, when he had a chill, and there was then mucopurulent expectoration. Physical examination showed dullness over the upper lobe of the left lung posteriorly, and over the lower lobe of the right lung. There was harsh bronchial breathing, with crepitant and subcrepitant râles generally over the chest, but most marked over the upper lobes. The heart's action was weak and rapid; the temperature varied from 99° to 103.5° F. The respiration was rapid, labored, and shallow. The urine was examined, but with a negative result. Five days after admission the patient became delirious, and shortly died. Miliary tubercles were found in both lungs at the autopsy, but at no place had cavities formed. The kidneys were the seat of tubercular deposits, and also in places of fatty degeneration; the tubercle bacilli were found in large numbers. The liver contained much fat, and also numerous young miliary tubercles. The case was interesting as showing the accuracy of diagnosis, confirmed by a post-mortem examination, and from the facts that both lungs were the seat of general tuberculosis without any cavities, and that the kidneys and the liver presented an excellent opportunity for the study of miliary tubercle at an early date.

TUBERCULOSIS OF LUNGS AND KIDNEYS WITH OBSCURE SYMPTOMS.—Dr. H. N. HEINEMAN presented the lungs and kidneys removed from the body of a German, twenty-nine years of age, who entered the hospital on the 23d of December, 1883. The family history was negative; he denied venereal disease; had never drunk to excess. Four years ago he began to have pain over the region of the bladder, occasional vesical tenesmus, and frequent micturition, the urine being cloudy but never bloody, and sometimes there was incontinence, while at other times the

catheter was required; there was more or less backache. Nine months before admission he had irregular chilly sensations. Four years previous to his marriage, which took place two years ago, he had been in the habit of masturbating, and since his marriage had had occasional involuntary emissions without erection. On admission there was no cough, nor any temperature elevation. He complained only of the genito-urinary symptoms. He was much emaciated and pale, the breath had a bad odor, some râles were heard generally over the chest, and there were a few areas of slight dullness, but no signs pointing to other than simple bronchitis; he died six days after admission. At first he passed from seventeen to twenty-seven ounces of urine during the twenty-four hours, but the quantity diminished to six ounces on the day of death. The specific gravity varied from 1.015 to 1.024, and the urine contained pus. At the autopsy adhesions were found over both lungs, which were studded with small, recent cheesy tubercles. There was bronchitis. The liver was cirrhotic. The spleen was increased in size and waxy. One kidney was over eight inches long and four inches and a quarter wide, and weighed two pounds, it contained cavities filled with cheesy and purulent material. The ureter was enormously dilated and thickened. The pelvis was not, as was usual in such cases, coated with a pyogenic membrane. The other kidney was the seat of hydronephrosis, the kidney tissue proper having almost entirely disappeared. The walls of the bladder were thickened, and coated with a thick layer of pus and cheesy material. The prostate was almost completely broken down. There was no urethral stricture. The point of interest in the case was the absence of a rise of temperature at any time during the course of an acute tuberculosis, although this was not of very infrequent occurrence. Again, the lung trouble seemed to be of recent date, while the genito-urinary symptoms were of long standing. Dr. Heineman was of the opinion that the hydronephrosis developed in the one kidney previous to and independent of the tuberculosis, and that probably the other kidney became hypertrophied during this time while having to do the work of both organs, and afterward tuberculosis developed.

ENLARGEMENT OF THE HEART.—Dr. HEINEMAN also presented a heart, which weighed thirty-seven ounces, from a man who gave a remarkably negative history. There were hypertrophy and dilatation, with acute ulcerative endocarditis. There had been no chill or febrile movement, but there had been dyspnoea. A systolic and a regurgitant murmur had been recognized at the base, and a presystolic and a regurgitant murmur at the apex.

PERNICIOUS MALARIAL FEVER.—Dr. G. L. PEARODY presented the spleen, liver, and brain of a man who had died of this disease. The liver and the spleen showed blood pigment in large amount to the naked eye; the brain-tissue in less degree. The pigment was entirely confined within the lumen of the blood-vessels within the brain, and probably also in the other organs, although their structure admitted less clearly of its demonstration. The man was thirty-one years of age, had been to Jamaica, from whence he arrived in New York on the first of January. He entered the hospital on the seventh, complaining of severe headache, and speedily relapsed into a condition of apathy, twenty-four hours later becoming comatose. Quinine was administered both by the mouth and subcutaneously. He died comatose. Shortly before death the temperature, which had previously been about normal, rose to 108° F.

Meeting of January 23, 1884.

GEORGE F. SHRADY, M. D., President, in the chair.

NEURO-FIBROMA COMPLICATING SPINA BIFIDA.—After several specimens had been presented for candidates for member-

ship, Dr. ELLIOT presented a specimen illustrating spina bifida complicated by a neuro-fibroma in which the fibrous element predominated. The case occurred in the practice of Dr. M. J. Roberts. [Dr. Roberts's account of the case was published in the journal for January 26th, p. 89.]

OVARIAN CYST AND HYDROSALPINX.—Dr. BROWN presented specimens illustrating these affections removed from two different patients. In the first case the patient, six weeks after the birth of her child, became retiring, and soon distinct symptoms of melancholia were manifest. She suffered a great deal of pain in the pelvic region, and had periodic hæmorrhages. At the last confinement there was considerable post-partum hæmorrhage, and she was some time in recovering. Pressure upon what was presumed to be a displaced ovary in Douglas's *cul-de-sac* caused her to shriek with pain. Dr. Dawson performed laparotomy, found the left ovary adherent and cystic, both Fallopian tubes dropsical, but the right ovary not displaced, as had been presumed. The diseased organs were removed, and the patient was greatly relieved. The other case was that of a woman who had suffered constant pain, referred to the pelvic region, for many years. Finally laparotomy was performed, and double hydrosalpinx was found. The patient had done well since the operation, and doubtless would ultimately entirely recover.

EPILEPSY (?) WITH VISCERAL LESIONS.—Dr. R. W. AMIDON presented a dilated stomach, an enlarged and congested spleen, congested kidneys with atrophied cortices, and a heart with the right ventricle dilated, with fatty substitution in its walls, the left ventricle being concentrically hypertrophied, with dilatation and thinning of the right auricle—all from a boy seven years of age, in whom the immediate cause of death was œdema of the lungs with heart failure. The child came of a neurotic family. He had measles at the age of three years, followed by general œdema. At the same time he began to have "spells," sensory in nature, which were supposed to be epileptic, and were treated by the physician in attendance with bromide of potassium, ten grains three times a day. Dr. Amidon saw the patient afterward, and remarked, concerning the apparent epileptic seizures, that the following facts were opposed to that view of their nature: First, the child sometimes had as many as seventy-two attacks in seventy-two hours. He did not believe that a patient could have so many true epileptic convulsions and yet maintain general health and a perfectly sound mind. Again, the child could remember better than the nurse the number of attacks which occurred during the day, and could always foretell them. Very few, if any, were preceded by a cry; the patient did not bite the tongue, nor did he froth at the mouth. There was preservation of sensibility during the attack, and there was resistance to opening of the eyelids—conditions which had led to the diagnosis of hystero-epilepsy, and to a favorable prognosis. When Dr. Amidon was called to see the patient, a bromide eruption had appeared on the legs, face, and forehead, but it rapidly disappeared on stopping the medicine. The remedies which he tried were the aqueous extract of opium, cannabis indica, quinine, iron, tonics, and regulation of the diet. At times improvement took place, but the appetite was ravenous, and doubtless led to indiscretions which rendered treatment ineffectual. Had dilatation of the stomach been known to exist in so great a degree he would have resorted immediately to hypodermic medication. It was probable that drugs administered by the mouth had remained in the stomach many hours without becoming absorbed. No lesion of the brain, which was finally developed, was apparent at the autopsy.

PLEURISY AND PERICARDITIS.—Dr. FERGUSON presented specimens illustrative of these affections, which presented their regular signs, in a man who died in the hospital.

"SURGICAL KIDNEY."—Dr. FERGUSON also presented specimens illustrating the affection known by this name. An interesting fact in the case was the condition of the leg, which had sustained an injury twenty years before, the exact nature of which the patient did not remember. At the autopsy the lower end of the femur was found largely expanded, the knee and the ankle joints were ankylosed, the arteries were atheromatous, and the muscles had undergone fatty degeneration.

DILATATION OF THE STOMACH.—Dr. J. C. PETERS was now able to present the stomach of a patient who had died since the narration of the case at a recent meeting of the society. The stomach was four to six times as large as normal, due to constriction of the pylorus. No tumor was present, and there was no sign of malignant disease.

CARCINOMA OF THE CRANIUM.—Dr. HEINEMAN presented specimens from a woman who had died in the Mt. Sinai Hospital at the age of about twenty-six years. In 1881 Dr. Mason extirpated a carcinomatous tumor of the right breast. On her admission recently to Mt. Sinai Hospital the diagnosis was made of carcinoma involving some one of the viscera. At the autopsy, however, the viscera were found normal. There were some infiltrated glands in the axillary and cervical regions. There were several tumors of the calvaria, one on the petrous portion of the temporal, causing considerable pressure upon the medulla, and one on the sphenoid, producing exophthalmus on the right side. The diploë was infiltrated, but the dura was not affected.

CARCINOMA OF THE STOMACH.—Dr. B. ROBINSON presented a specimen of carcinomatous tumor of the pyloric orifice of the stomach, the interest of the case consisting in the fact that at certain times the tumor lay behind the liver in such a way that it could not be discovered by palpation, while at other times it assumed a position in which it could easily be detected through the abdominal walls.

COMBINATION OF LIPOMA AND EXOSTOSIS.—Dr. J. A. WYETH presented a specimen consisting in part of bone and in part of fatty structure, possibly constituting the rare condition of osteo-lipoma, but few cases of which had been placed upon record. The tumor was removed from a woman fifty years of age, and was situated upon the radius about one inch from the carpal articulation. The fatty tumor, consisting of two lobules of considerable size, was connected with the small bony exostosis by means of a pedicle. He was inclined to accept the view suggested by the president, that the lipoma developed independently of the bony tumor, and that their connection was accidental.

NEW YORK SURGICAL SOCIETY.

Meeting of January 22, 1884.

ROBERT F. WEIR, M. D., President, in the chair.

HABITUAL DISLOCATION OF THE ULNAR NERVE; MYOSITIS.—Dr. F. LANGE presented a patient, a violinist, who, about a week before, immediately after more than his usual amount of labor, began to suffer from a severe pain in the muscles of the right forearm near the elbow joint, and especially very near the internal condyle. The severe pain lasted only a short time, but the pain did not cease entirely. It increased during the next two days, after repeated use of the arm, and on the third day was again so severe that every movement at the elbow joint was impossible, and the patient suffered intensely. He was under medical treatment for a number of days, and he called to see Dr. Lange the Saturday before the meeting, when it was noticed that there was some swelling corresponding to the muscles of the forearm which take their origin from the internal epicondyle, and there was a very tender spot at the end of the ridge through which the ulnar nerve passes. Closer examination de-

termined the existence of luxation of the ulnar nerve between the olecranon and the internal condyle at every attempt to flex the forearm. The nerve could be traced quite distinctly, and rolled freely under the thumb and finger, so that in the semiflexed position it would be dislocated around the protruding point of the epicondyle. The most painful point, however, was where the nerve enters the muscles. In the left arm also the ulnar nerve could be easily moved under the thumb and finger, and the question arose whether the difficulty in the right arm pertained primarily to the nerve or to the muscles. Dr. Lange thought, however, that the case was one of myositis involving the muscles which have their origin in the region of the internal condyle, and thought, perhaps, also the sheath of the nerve had become involved. There were no peripheral alterations pointing to a lesion of the nerve itself.

EXCISION OF THE ELBOW JOINT.—Dr. LANGE also presented a patient in whom he had excised the left elbow joint nine months before. She was presented for the purpose of exhibiting an apparatus, described some years ago, which he had used after this operation with considerable advantage, and which he regarded as useful, especially in those cases in which a great deal of bone had been removed and the new formation was comparatively small, and also where a great deal of abnormal mobility existed. The idea involved in the apparatus was that some slipping of the bones should be allowed, so that those of the forearm were somewhat forced backward, and an adjustment of them was effected which imitated their physiological apposition. At the same time the joint was kept in semiflexion by means of rubber strings. The exercises were done by trying to keep a weight grasped with the fingers and not to allow it to extend the forearm. In this way the point of support was transferred to the attachment of the rubber strings. A lever action took place by which the bones of the forearm were still more brought into coaptation. The weights must be chosen so that they were slightly too heavy, and slowly pulled the arm into the extended position. Active extension alone was practiced in applying artificial flexors. He thought that, after the apparatus had been worn for a year or more, functional ability of the forearm would be very much improved.

Dr. J. C. HURCONSON inquired whether the motions of the forearm without the apparatus had improved any.

Dr. LANGE said there had been improvement, but it was very slight, and the movements of the forearm were very uncertain without the apparatus, which had been worn for a short period of time only, the patient not having had any orthopædic treatment for a number of months.

Dr. J. L. LITTLE referred to a case in which he excised the elbow joint and the instrument-maker constructed a similar apparatus, which had enabled the patient to use her hand ever since she began to wear it. While wearing the apparatus she was able to accomplish considerable work, but, when it was removed, the arm was perfectly useless and hung by her side. The apparatus did not permit of the slipping of the bones like that exhibited by Dr. Lange.

REPEATED AMPUTATIONS OF THE LOWER LIMB.—Dr. A. G. GERSTER presented a man, forty-eight years of age, on whom three amputations had been performed. At the last one the patella, both condyles of the femur, together with a portion of the old cicatrix, which was attached firmly to the posterior surface of the condyles, were removed. About a year ago the man suffered from compound fracture of the ankle joint, which was not treated antiseptically. A phlegmon developed, and it became necessary to amputate the leg. Both of the flaps, however, sloughed, although the amputation was treated by the open method. Dr. Gerster attributed the sloughing to the bad condition of the patient's circulation, due to habitual alcoholism.

As there was no covering for the protruding extremities of the bones, and it was expected that the cicatrix would become ulcerated, amputation was performed a second time at the knee joint by another surgeon. Most of the long anterior flap after this operation also sloughed, and the result was a large cicatrix upon the posterior aspect of the limb, closely adherent to the bone, and the final amputation already mentioned was performed. Dr. Gerster presented the patient especially on account of one pathological observation. When he had laid bare the condyles by the circular incision he found that, instead of close union of the integument having taken place with the articular surface, a bursa mucosa existed between it and the cartilage. The amputation having been accomplished, Neuber's deep sutures were employed, one drainage-tube was placed in the cavity from which the patella had been removed, and only one sublimat-sawdust dressing was necessary. Four weeks after the amputation the man was able to walk on the stump, and was discharged from the hospital. The wound at the amputation was quite extensive and irregular, and about eleven sutures were introduced to bring about contact of the walls of the cavity. With the patella the lining of the bursa quadricipitis was also removed.

DOUBLE BOW-LEGS; MACEWEN'S OSTEOTOMY.—Dr. GERSTER also presented a boy, sixteen years of age, showing the result of double osteotomy, according to Macewen's method, for bow-legs. Nine weeks had elapsed since the operation, and the case had progressed without any complications. The operative wounds were treated with a small pad of iodoform gauze. The distance between the internal condyles was three inches and a half before the operation, and now they touched each other. There was considerable arterial hemorrhage on one side, and he was obliged to ligate the bleeding vessel *in situ*. The limbs were placed upon simple straight splints and allowed to remain four weeks, when the splints were removed, a silicate of sodium dressing was applied, and the patient was allowed to walk about on crutches.

Dr. LANGE said he saw the last patient before his admission to the hospital, and so far as he remembered, it was a case of genu varum, the principal deflection being, as it was now, in the course of the tibia. He thought it would have been better if an osteotomy had been done below the tuberosity of the tibia.

Dr. GERSTER said that some of the deformity was due to curvature of the thighs, and his purpose was to determine whether or not it was necessary to osteotomize both femur and tibia, but, finding that the osteotomy of the femur corrected the deformity, he proceeded no further. Doubtless there was a marked curvature of the tibia also, but he considered the result as a very fair one.

Dr. C. T. POORE asked if the femoral curve was the more marked of the two.

Dr. GERSTER replied that the tibial curve was the more marked.

Dr. POORE remarked that in genu varum the deformity was due chiefly to the tibial curve, and he supposed quite probably one difficulty in correcting it in this case was the loose condition of the ligaments; on this account it was very difficult to correct the curvature.

Dr. GERSTER said that he had no difficulty in correcting the deformity after the bones were snapped.

Dr. LANGE remarked that there now existed a slight degree of knock-knee, and the curvature of the tibia remained.

ON THE VALUE OF INTERNAL ŒSOPHAGOTOMY IN THE TREATMENT OF CICATRICAL STRICTURE.—Dr. HENRY B. SANDS read a paper with this title, the concluding portion of which is given in this number of the journal. [See p. 209.]

Dr. POST remarked that Dr. Sands had suggested, as prophylactic

treatment, that dilatation should be commenced a week after the injury. He would suggest that a week would be rather early, and that two or three weeks would be better, as it was only after the separation of the sloughs, and when the reparative process had become well established, that the contraction began to take place.

Dr. SANDS remarked that his patient was about the house and apparently in pretty good health four days after the injury, and he would prefer to give, as a rule, too early rather than too late a period.

The PRESIDENT remarked that it had been his good fortune to witness the operation of Bergman, described in the paper, where the gastric fistula made for the relief of a strictured œsophagus was closed after the stricture had been dilated. It certainly was a unique and remarkable case. One point in connection with the paper he thought worthy of remark was the omission of continuous dilatation. He had not had any personal experience with cicatrival strictures as tight as Dr. Sands had cited, but he had had some experience in the treatment of quite narrow malignant strictures. Recently, in one instance, a No. 18 soft catheter was kept in position three weeks prior to the death of the patient, and with great comfort and improvement in the size of the strictured portion, though nourishing the patient was the only point aimed at in the case. He was led to adopt this method of treatment by reading an article by Krishofer, who had employed continuous indwelling of the catheter for great lengths of time, in one instance the instrument remaining in position for one year without any detrimental result. The comparison with reference to dilatation was often made between the urethra and the œsophagus, but erroneously, for in the former there was present an irritating or septic urine. Dr. Weir thought it had been shown by Krishofer's case that the œsophagus bore continuous dilatation better than the urethra, and the food, being carried inside of the tube, could not produce irritation. He would therefore, in cases of cicatrival contraction, first try this method of dilatation before resorting to operative procedures.

REMOVAL OF FOREIGN BODIES.—Dr. W. S. HALSTED presented several foreign bodies, with brief histories of the cases in which they were removed.

CASE I.—*A Piece of Fibro-Cartilag removed from the Œsophagus by External Œsophagotomy.*—At Ward's Island, July 23, 1882, a Hungarian, aged thirty-three, swallowed at dinner a piece of food which became arrested in his œsophagus a little below the cricoid cartilage. The resident physicians were unsuccessful in their attempts to dislodge it. They obtained, however, a fragment which, submitted to microscopical examination, proved to be fibro-cartilage. The patient was said to have experienced great difficulty in breathing for several hours, and then to have become quite tolerant of the foreign body, but to have been unable to swallow even liquids.

July 25th.—The foreign body, indistinctly definable by palpation of the neck, was believed to be lodged in the œsophagus, just above the sternum, projecting more to the right side than to the left. An incision, extending from the middle of the thyroid cartilage to the interclavicular notch of the sternum, was made parallel with the anterior border of the sterno-cleido-mastoid muscle. The oblique jugular vein was drawn toward the median line. The middle thyroid vein in the upper angle of the wound was doubly ligated and divided. The common carotid artery, crossed by the omo-hyoid muscle, rolled up into view. The foreign body was readily mapped out through the œsophageal walls, and over it was stretched the recurrent laryngeal nerve. An incision an inch and a quarter long was made into the œsophagus, parallel with and posterior to the nerve, and the foreign body, measuring $1\frac{1}{2} \times 1 \times 1$ inch, was removed with a vulsella.

The wound in the œsophagus was united by sulphurous-acid catgut, and the integument by silk sutures. An iodoformized peat dressing was applied. A few days later the patient was clandestinely served with blackberries by missionaries to the island, which interfered with union by first intention, but otherwise did not hinder his prompt recovery.

CASE II.—*Three Calculi, each with a Portion of a Soft Catheter as a Nucleus, removed from the Bladder by Lateral Lithotomy at One Operation.*—The patient, a Finn, about thirty-five years old, had been in the habit of evacuating his paralyzed bladder with a soft catheter. One day the catheter broke off in his bladder, and a piece, believed to be two or three inches long, was left behind.

He subsequently regained the power of his bladder, and applied, six or eight months after the mishap, at Ward's Island, for relief of frequent and painful micturition. A stone was detected by Thompson's searcher. In consideration of the history, it was believed to be advisable to practice the cutting operation. The patient had such a short perineum that the finger, introduced into the bladder, could ascertain the number and shape of the stones. These were carefully so seized with the forceps as not to be crushed, and removed.

The patient's convalescence was somewhat protracted because of a cystitis perpetuated by a few fragments, which he eventually passed *per urethram*.

Each calculus contained a piece of the catheter, its point being distinctly visible in one of them.

CASE III.—*A Portion of a Bullet removed from the Diploë and Cranial Cavity.*—Mr. H. U. G., aged fifty-two, was admitted to the Chambers Street Hospital, May 9, 1883, for a self-inflicted pistol-shot wound of the head.

A small circular scalp-wound was found on the right side, two inches and a half below the sagittal suture and one inch in front of the external auditory meatus. The reflexes were normal, and there was no paralysis; the intellect was perfectly clear.

A crucial incision was made through the scalp. The external table was found depressed, and at the bottom of the depression there was a hole one quarter of an inch in diameter and about one inch behind the bullet wound in the soft parts. A probe, passed obliquely backward through the hole, detected the foreign body, which was not visible.

Thereupon certain fragments of the external table were removed, and the bullet was revealed, lying between the two tables, and projecting somewhat into the cranial cavity. Upon its extraction, a slightly depressed fragment of the inner table was withdrawn.

The wound was dressed antiseptically, and closed with a continuous catgut suture. Union took place by first intention throughout, except where the incisions crossed one another—viz., at the point of entrance of the bullet—and here there was a very slight necrosis of the approximated corners of the flaps.

The bullet had split upon the outer table of the parietal bone; one fragment entered the diploë and cranial cavity, as described, and the other passed through a mirror and was found behind the bureau.

Dr. HUTCHINSON said that some time ago he presented a urinary calculus to the society which had for its nucleus a loop of silver wire. The patient had a urethro-vesical fistula, which had been closed with silver-wire sutures, and he (Dr. Hutchinson) was reported to have stated that a house surgeon who had been directed to remove the sutures overlooked one, which fell into the bladder and formed the nucleus of the stone. This was an error. He had said that he had himself removed the sutures, and was responsible for having failed to remove the one which entered the bladder.

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M.D.,

LECTURER ON OPHTHALMOLOGY AND OTOTOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN AND TO THE NURSERY AND CHILD'S HOSPITAL.

(Continued from page 159.)

OCULAR TROUBLES DURING PREGNANCY AND CONFINEMENT.—Métaxas ("Recueil d'ophtalmologie," Oct., 1883) divides his subject, as Power did, into four classes, viz.: 1. Affections of the eye due to anæmia and general weakness, such as corneal ulcers, accommodative asthenopia, and cataract. 2. Affections of the eye caused by a special lesion of the nervous system, such as diseases of the retina and optic disc, optic nerve, chiasm, and central ganglia. 3. Retinitis albuminurica, hæmorrhages, and exudation into the retina. 4. Ocular diseases from causes still unknown. Ulcers of the cornea are very apt to occur during lactation. Iritis has frequently been met with during pregnancy and after confinement, and so have accommodative asthenopia and cataract. Métaxas adopts Pasteur's theory that puerperal fever is due to the presence of minute organisms or microbes, the germs of which, floating in the air and cultivated in the fluids which bathe the genital organs of the parturient woman, are introduced into the circulation and give rise to septic troubles, and among them to panophthalmitis and iridochoroiditis. These organisms do not develop so long as the blood is in motion, but only when the micrococci meet with an obstructed vessel in their course.

THE TREATMENT OF SUPPURATION AFTER EXTRACTION OF CATARACT.—Abadie ("Annales d'oculistique," Sept.-Oct., 1883) here reiterates his belief in the value of galvanic cauterization of the lips of the corneal wound as soon as any signs of suppuration appear. He touches with the point of the galvano-cautery the center of the corneal wound, and also the two extremities. He then opens the anterior chamber with the point of a Weber's knife, and evacuates the aqueous humor. Every three or four hours the eye is to be washed with a saturated solution of boric acid. The cauterization provokes but slight reaction; it is not very painful, and at the end of an hour or two the pain subsides. In twelve or fifteen hours an evident amelioration appears. The chemosis and swelling of the lids diminish, and the cornea becomes more translucent. At the end of twenty-four hours, however, the cauterization must be repeated. Twelve hours later there is another return of the inflammatory process, which demands another cauterization, and this must be repeated for five or six days, at the end of which time all danger is past.

TREATMENT OF GLAUCOMA BY LACERATION OF THE EXTERNAL NASAL NERVE.—Badal ("Annales d'oculistique," Sept.-Oct., 1883) describes the method of operating, and compares the results of this method with those obtained by iridectomy and sclerotomy. He bases his conclusions upon twenty eyes thus operated upon. An analysis of these cases and of five cases of Abadie's shows that laceration of the external nasal nerve lowered the tension in nineteen. In twenty cases in which the glaucoma was acute or subacute the operation put a stop to the pain, sometimes instantaneously. In four of these cases an iridectomy had aggravated the condition of the patient, while in two cases a sclerotomy had changed a chronic glaucoma into an acute attack. In six other cases sclerotomy had failed, and iridectomy in four. In two cases of acute glaucoma, the cure was rapid and complete in one, while in the other there

was no improvement of the vision. In six other cases in which the vision had been lost, or nearly so, for a long time, the visual acuity was so far improved in three cases as to permit of the patients' going about alone. In the cases in which the laceration of the nerve had failed, both sclerotomy and iridectomy also proved futile. In no case did the laceration of the nerve aggravate the condition of the patients.

ANTISEPTIC OCCLUSIVE DRESSINGS IN OPHTHALMIC SURGERY.—Gillet de Grandmont ("Annales d'oculistique," Sept., Oct., 1883) recommends the following dressings as antiseptic: First, a piece of cotton wadding and hygroscopic gauze, large enough to cover the eyelids, about five centimetres long and three wide. This is laid over the closed lids and covered by another piece of double thickness. Over this is laid a layer of carbolized gauze eight centimetres long by six broad. Between the hygroscopic gauze and the lids he places a few boric-acid crystals. When the carbolized gauze is in place, a brush dipped in elastic collodion is immediately passed all round its edge, and the agglutination to the skin of the forehead, temple, and cheek is immediate, and thus the eye is hermetically sealed. No bandage is required, and the dressing may be left undisturbed for three or four days.

THE HYGIENE OF VISION AND THE INCANDESCENT ELECTRIC LAMP.—Meunier ("Recueil d'ophtalmologie," Sept., 1883) has been experimenting with the illuminating power of incandescent electric lamps, and formulates his conclusions as to its effects upon the hygiene of vision as follows: 1. The retina is as sensitive to the ultra-violet rays as to the visual rays. 2. It is impossible to pronounce upon the question whether the retina is sensitive to the ultra-solar rays, arrested always by the cornea and vitreous humor. 3. It is the lens alone which limits the visual spectrum. 4. The ultra-violet rays being absorbed by the media of the eye, this absorption probably fatigues the organ, especially when it is a question of the long and brilliant ultra-solar spectrum of the electric arc. 5. Photographs of the spectrum of incandescent electric lamps have shown that this spectrum scarcely exceeds the visible spectrum. Hence this light spares the media in front of the retina all the work of absorption and dispersion of the ultra-violet rays. 6. This species of light being fixed and giving out but little heat, it should be employed in schools, offices, work-shops, and in all places where work is carried on for long hours by artificial light.

CONJUNCTIVAL GRAFTING.—Cuignet ("Recueil d'ophtalmologie," Sept., 1883) reports an instance of conjunctival grafting in a case of burn of the conjunctiva with extensive symblepharon in a boy aged thirteen. About three years before the patient received a burn from quicklime in the left eye. The lower lid was adherent to the eyeball from the bottom of the cul-de-sac to its ciliary margin, throughout the middle three fifths of its length, thus involving both sclera and cornea. Cicatricial contraction had brought the edge of the lid three millimetres above the lower margin of the cornea, and the band of symblepharon was thick, short, and resisting. The lid was separated from its bulbar attachments by scissors without disturbing the insertion of the inferior rectus muscle. The dissection was carried carefully to the bottom of the cul-de-sac. A piece of mucous membrane was then carefully removed from the buccal cavity of a rabbit, large enough to cover the raw surface on the lid and on the eyeball, dipping down to the bottom of the cul-de-sac and maintained in position by sutures along the margins, and the cul-de-sac was made by passing sutures deep down at the bottom of the groove and bringing them out through the skin at the inferior orbital margin. A slight compress was then applied externally and covered by a simple bandage. On the fifteenth day an examination showed that there were no adhe-

sions between the lid and the eyeball; the eyeball was freely movable, and the cul-de-sac had retained about one half of its normal depth. The thick cicatricial pterygium had disappeared, and the opacity of the cornea only covered the lower portion of the papillary field. One year later the patient was seen, and the result had remained unchanged.

DIABETIC PARALYSIS OF THE ABDUCCENS.—Guttmann ("Centralblatt für prakt. Augenheilkunde," Oct., 1883) reports a case occurring in the person of a physician, aged fifty-three, who was suffering from general muscular weakness, and who thought he had tabs. He began to see double in May, 1883, while playing a game of chess. Hirschberg found paralysis of the right abduccens, normal vision and accommodation, and normal pupillary reaction. There was a large amount of sugar in the urine. On May 16th the abduccens paralysis was complete, and secondary convergence had appeared. After a sojourn of two months in Carlsbad, the diplopia had almost entirely disappeared, there was no convergence, and the sugar had entirely disappeared from the urine.

CONGENITAL LIPOMATOUS DERMOID TUMOR OF THE EYEBALL.—Hirschberg and Birnbacher ("Centralblatt für prakt. Augenheilkunde," Oct., 1883) report a case of this nature in a young woman aged eighteen. There was a bright yellow, smooth projection which covered the greater portion of the external half of the sclera of the left eye. It was separated from the healthy conjunctiva near the corneal margin by a tolerably deep groove, but downward and outward it merged gradually into the normal curvature of the eyeball, and was distinctly separated from the lachrymal gland. It was carefully dissected out from the sclera and conjunctiva. The vertical elliptical defect, left after its removal, was closed by three sutures. The external rectus muscle was not injured. The tumor was eighteen millimetres long, ten wide, and seven thick. It was covered by several layers of epithelium. There were several slightly pigmented small hairs on its surface, and the hair follicle and sebaceous glands were perfectly formed. A careful microscopical examination proved the tumor to be dermoid in character and to belong to the group of teratomata.

SPONTANEOUS GANGRENE OF THE SKIN OF THE EYELID.—Hilbert ("Centralblatt für prakt. Augenheilkunde," Oct., 1883) reports a case of this rare disease in a female child, four months old, in apparently perfect health, and with healthy parents. In the center of the right upper lid there was a yellowish scab of circular form and about five millimetres in diameter. The skin immediately surrounding the scab was slightly reddened. After the removal of the scab the skin was found deprived of its epidermis and slightly moist, resembling an eczema impetiginosum. Two days later the entire upper lid was very much injected and cedematous; the slough had doubled in size, and there was some fever. There was a swollen lymphatic gland at the angle of the jaw on the right side. The urine contained neither sugar nor albumin. During the next four days the disease advanced still farther, the original site of the scab became dry and black, and a line of demarcation formed round the entire periphery of the focus of disease. The necrotic portion of skin was also circular, became black and dry, and had a diameter of nineteen millimetres. Two days later this was removed with the forceps, and the fever had disappeared. Granulations soon appeared, and, under powdered iodoform, the raw surface had entirely healed in a week.

XEROSIS OF THE CONJUNCTIVA, INFANTILE CORNEAL DEGENERATION, AND THE ORIGIN OF XEROPHTHALMUS.—Lohr's article ("Arch. f. Ophthalmologie," xxix, 3) is long and interesting, but difficult of clear abstraction. He first considers infantile xerosis with ulceration of the cornea, which he illustrates by one case. In this case the ocular conjunctiva and the mucous mem-

brane of the pelvis of the kidneys were the seat of a hypertrophic, desquamative epithelial affection, and of an enormous development of a peculiar schizomyces or fissured fungus. There was also present a purulent destruction of the cornea with subsequent panophthalmitis, which was the means of introduction of this fungus into the corneal tissue and interior of the eyeball. The epithelial change was of a hyperplastic character, with repeated stratification of numerous thin epithelial scales, which repeatedly scaled off and were followed by new epithelial formation; the cells were themselves hypertrophied and their hooked processes larger. There was also present a kind of fatty degeneration, most marked in the more superficial cells and immediately around the nuclei. Leber then discusses the xerosis which occurs with hemeralopia, which he finds appears under the same conditions and with the same complications as the infantile form. During its entire course there may be no disturbance of the general health; but, if there is any disturbance of nutrition present, the lesion in the eyes is so much the more destructive. Leber then describes a more or less pronounced, general partial xerosis which is a purely local, secondary lesion, occurring in eyes which have been the seat of chronic conjunctivitis or keratitis, but without much shrinking of the conjunctiva. In this form of xerosis Leber found not only an hypertrophied condition of the epithelium, but also fatty degeneration and the peculiar fungous growth heretofore mentioned. The article concludes with some interesting remarks upon the origin of xerophthalmus.

UNILATERAL TEMPORAL HEMIANOPIA AFTER TREPHINING.—Nieden's case of temporal hemianopsia, following an operation of trephining for pus ("Arch. f. Ophthalmologie," xxix, 3), is very interesting. The opening made by the trephine was close to the base of the left occipital groove and very near the bony ridge running upward from the internal protuberance. Just at this point rests the posterior end of the left occipital lobe, and, as the dura mater was injured at this point by the trephine, it is probable that the portion of cerebral cortex lying just beneath was lacerated, and, in the course of the next few weeks, prolapsed into the wound, was destroyed, and sloughed off. The defect of vision of the right eye, first noticed on the regaining of consciousness after the operation, was no doubt due to the injury of the left occipital lobe. As the chief symptom was the loss of the greater part of the visual field of the right eye—that is, its entire temporal half—this region of the left occipital lobe must constitute the visual center for the greater part of the retina of the right eye.

THE DECROSSING OF THE OPTIC-NERVE FIBERS IN THE CHIASM AND OPTIC TRACTS.—Burdach ("Arch. f. Ophthalmologie," xxix, 3) gives the results of an examination of the optic nerves and tracts in a case in which one eye had been enucleated some years before. The atrophy of the nerve fibers could be traced from the eyeball backward to the tracts. The uncrossed bundles appeared as narrow, non-medullary zones on the upper and outer sides of the supero-external and on the outer side of the inferior quadrant. The crossed bundles appeared as narrow atrophic streaks or lines along the lower margin, with a wedge-shaped expansion in the infero-nasal quadrant. The case corresponded in the microscopical appearances with the other cases hitherto published.

A PECULIAR CORNEAL CHANGE DEPENDENT UPON THE INFILTRATION OF A FUNGOID DEPOSIT IN THE CORNEA.—Baumgarten ("Arch. f. Ophthalmologie," xxix, 3) describes a peculiar pathological appearance in the cornea of an eye removed for beginning sympathetic inflammation in the other eye. Nearly the entire cornea was of a grayish-green color, the opacity depending upon an infiltration of what looked like masses of fungus. These bodies were brilliant, with sharp borders, colorless, close-

ly pressed together, and were either elongated like rods or a long oval in shape. The largest number of these bodies were in the center of the cornea. The strongest argument against the mycotic character of this corneal disease was the total absence of all signs of inflammation and degeneration of the corneal tissue.

GLAUCOMA.—Jacobson's article ("Arch. f. Ophthalmologie," xxix, 3) is one of considerable interest. He goes back to the consideration of Mackenzie's theory of six periods in the course of glaucoma, with special reference to the first two, viz.: 1. A green reflex behind the pupil with movable iris and good vision; and, 2. A dirty gray lens, sluggish iris, diminution of vision, and a somewhat hard eyeball. In both these periods the glaucoma is a disease of the lens, if amaurosis has not previously appeared; but in all the other periods all the tissues of the eyeball are involved. He therefore regards Mackenzie as the author of the hypothesis of increased tension. He then considers this hypothesis and that of an existing choroiditis. From his own observations and those of other authors, he thinks that there is an essential difference between the process of progressive nerve atrophy in the trunk of the optic nerve and the changes in the axis-cylinders dependent upon compression of the papilla. The course of the functional disturbance is now explained by assuming that, in opposition to genuine and to extra-ocular pressure atrophy, there are not in the beginning a very large number of the optic-nerve fibers which are in a high degree incapable of conducting power; but that certain laterally deviating or especially protected fibers of the papilla suffer but little from the gradually increasing, periodically variable intra-ocular tension. These fibers, however, lose their conducting power very rapidly when the tension becomes too great, or when the conditions are very unfavorable to a lateral deviation or yielding. Jacobson then considers briefly the influence of psychic disturbances and irritation of the trigemini in developing increased tension, and illustrates the effects of such causes by cases. He next takes up the subject of prodromal and chronic glaucoma from the clinical standpoint. In regard to the latter, he calls attention to the fact that the marginal excavation is not an early but a late symptom of glaucoma, which is always preceded by a stage of displacement of the vessels backward upon the surface of the papilla and toward the marginal excavation. He also calls attention to the fact that experience teaches that with frequently recurring attacks, despite their transient character, loss of function occurs without the outbreak of an actual acute glaucoma; and hence our attention should be especially directed toward the prodromal symptoms. Chronic glaucoma may be far advanced before any displacement of the vessels at the margin of the disc occurs. The marginal excavation always precedes the deep, central excavation demonstrable with the ophthalmoscope. Jacobson thinks that a permanent, excessive spasm or tension of the muscle of accommodation may become a cause of prodromal and chronic glaucoma.

A PECULIAR APPEARANCE OF THE INHERENT LIGHT OF THE RETINA.—Mayerhausen ("Archiv für Augenheilkunde," xiii, 1) gives an account of a peculiar phenomenon which he observed under certain conditions in his own eyes. The phenomenon consisted in general in the appearance of groups of absolutely parallel bright lines, with regular dark intervening spaces, which were visible upon a dark wall at a distance of five metres. The width of these lines was from two to four mm., and their distance from each other from one to one and a half cm. Between these bright lines were an indefinite number of less bright, much finer lines. The direction of these lines was very different in different portions of the field of vision. These lines were absolutely immovable, but remained at the same spot as long as they were visible. Occasionally they could be seen extending

all over the visual field. A very dark background was by no means necessary for their perception, for he was finally able to see them in broad daylight. These lines Mayerhansen regarded as a perception or observation of the proper or inherent light of the retina, appearing in a very definitely regular form, harmonizing with an actual anatomical substratum.

OPERATIONS FOR ENTROPION.—Holtz ("Archiv für Augenheilkunde," xiii, 1) claims for his operation the following advantages: 1. It effects its object without the slightest shortening of the skin of the lid. 2. It is therefore applicable in cases in which, on account of previous shortening of the skin, other methods can not be employed. 3. It does not change the shape of the lid, nor does it obstruct in any way the opening and closing of the lids. 4. In cases of relapse, it may be repeated without disturbing the external appearance of the lids in the slightest degree. 5. The tension of the skin, which restores the edge of the lid to its normal position, remains the same, whether the lid is lifted or lowered.

FENESTRATED EXCISION OF THE IRIS.—Nicati ("Archives d'ophtalmologie," Sept.-Oct., 1893) gives the following reasons for performing a fenestrated excision or a simple incision of the iris at the level of a peripheral section of the cornea: 1. It assures the flow of the aqueous humor from the posterior chamber by direct capillarity. 2. Consequently it maintains an equilibrium of tension of the two chambers. 3. It does away with the principal cause of the inclosure or adhesion of the iris in the wound. The advantages accruing from the integrity of the sphincter are: 1. The easier and more complete reduction of the iris. 2. The disengagement of the angle of the anterior chamber by the stretching of the iris—an essential point for the maintenance of the filtration of the ocular fluid. 3. The preservation of the æsthetic and functional advantages of a normal pupil.

DISTICHIASIS, TRICHIASIS, AND ENTROPION.—Nicati ("Archives d'ophtalmologie," Sept.-Oct., 1893) concludes, from his observations upon a large number of cases, that distichiasis, or a supernumerary row of eyelashes, is a congenital condition, and can only be cured by ablation. Trichiasis, or deviation of the eyelashes by destruction of the margin of the lid, demands a plastic operation upon the edge of the eyelid. Entropion, or deviation of the eyelashes by a rocking of the edge of the lid and destruction of the conjunctiva, demands an operation for un-warping or straightening; resection of the tarsus when the disease is stationary; advancement of the elevator when relapses or fresh onsets of inflammation are to be feared.

CONGENITAL LESION OF THE RETINA.—Gayet ("Archives d'ophtalmologie," Sept.-Oct., 1893) reports an interesting case of what was possibly congenital retinitis pigmentosa in a young man of sound health, who had had defective vision since early infancy. His parents were first cousins. He had two brothers and a sister with normal vision, and one younger sister with the same trouble as he had himself. The patient had never been able to find his way in the dark, or in places obscurely lighted. His senses of hearing, taste, and smell were perfect, yet he had never been able to sing or whistle any tune. He had a myopic astigmatism of two dioptics in the horizontal meridian. The visual field of the right eye was concentrically limited; that of the left eye was less limited and more irregular. Colors were only perceived by the patient in a very narrow field, and even here there was a certain amount of dyschromatopsia. The media were perfectly clear. The macula was much larger than ordinary. There were a large number of white spots all over the fundus, most of them circular and slightly elevated, and increasing in size from center toward the periphery. There was no displacement or accumulation of pigment at any of the spots, and the retinal vessels all passed in front of the spots. Gayet thought

them to be at the level of the limitans interna of the choroid and of the hexagonal pigment-cell layer. He thought that this mother-of-pearl appearance had actually taken the place of the pigment, and hence he regarded the lesion as one of transformation. The same condition existed in the eyes of the younger sister.

RHEUMATIC INFLAMMATION OF THE CAPSULE OF TENON.—Sédan ("Recueil d'ophtalmologie," September, 1893) reports a case of this nature and gives his method of treatment. The case occurred in a man, aged thirty-four, who had been subject to repeated attacks of acute articular rheumatism. In the present attack, the lids of both eyes were swollen, there was extensive chemosis, so that the movements of the eyes were interfered with, and the lids could with difficulty be closed. The cornea were slightly cloudy, and there was slight exophthalmus. He scarified the lids and conjunctiva freely and applied hot elder-water compresses. The next day the exophthalmus on both sides was very marked. He repeated the scarifications, and through one of them, near the external canthus, there issued a quantity of a light yellow, almost oily liquid. An incision in a corresponding spot on the other eye gave exit to a similar fluid. Through these two wounds a permanent filtration was established, which greatly reduced the swelling and the protrusion of the eyes. An ophthalmoscopic examination showed no change from the normal in the fundus. For five days these fistulous openings discharged freely; the eyes gradually receded into the orbits, and the ocular symptoms slowly subsided, to give place to the symptoms of an attack of acute articular rheumatism.

JEQUIRY AND ITS FAILURE IN THE TREATMENT OF CONJUNCTIVAL GRANULATIONS.—Parisotti and Galezowski ("Recueil d'ophtalmologie," August, 1893) have not succeeded as well with infusions of jequiriy in the treatment of granulations as Wecker and others have. They obtained their infusion of the beans from the same pharmacist who furnished Wecker with his infusions; and they employed it with rigid regard to the directions given by Wecker; but they produced only negative results. They noted the appearance of a completely smooth surface of the conjunctiva where the granulations had been, but at the end of two weeks the lids had almost regained their normal thickness, and the granulations had remained completely intact. If the conjunctival surface be examined before the swelling has entirely disappeared, there will be seen a united, almost glistening surface, resembling cicatricial tissue, but which is only caused by the swelling of the tissues. During this period the granulations remain concealed by the swelling of the mucous membrane; but, as soon as the inflammation has completely disappeared, the granulations will be found in their primitive state, without having undergone any modification. Moreover, they think that this method of treatment is not without danger to the cornea, which may be even entirely destroyed.

(To be concluded.)

Miscellany.

THERAPEUTICAL NOTES.—*The Action of Papayotin and Papain*.—According to Professor Rossbach ("Zeitschr. f. k. Med.," vi Bd., 6 Heft, 1893), the *Carica papaya*, or papaya tree, is a native of South America, but is cultivated also in other tropical countries, and can be raised elsewhere in hot-houses. Its wood, leaves, and berries contain a great abundance of milky juice, which flows freely from an incision in the trunk, and hardens on exposure to the air. From this juice is obtained, by precipi-

tation with alcohol, that peculiar digestive ferment which Würtz and Bouchut have denominated papain. It has been shown by these experimenters that a given quantity of papain is capable of dissolving one thousand times its own weight of moistened fibrin, almost the whole of which it transforms into a peptone, and that its digestive action is similar in all respects to that of natural pepsin. It is also proved that this liquefaction of fibrin is in no degree due to the bacteria which are propagated with great rapidity in the papain solution.

Professor Rossbach has found: 1. That hot concentrated solutions of papayotin exert their solvent powers no more speedily than cold ones. 2. That the flesh of newly killed rabbits, when placed in a five-per-cent. solution of papayotin, becomes soft and sometimes quite disintegrated, in half an hour, while pulmonary tissue, on the contrary, is scarcely acted upon, and living mucous membrane is not in the least affected. 3. That very weak preparations possess but little solvent power; hardly any perceptible effect is produced by a one-half-per-cent. solution. The digestive energy of papayotin is lessened by the addition of either hydrochloric acid or phenol, but is not entirely destroyed even when these agents are used in the proportion of four per cent.

No ill effects were produced on dogs, cats, or rabbits, whether healthy or diseased, by the ingestion of papayotin in large quantities. In some cases the appetite was greatly increased. In those animals which were killed after partaking of the drug, the mucous membrane of the stomach and oesophagus showed not the slightest alteration.

From these and other similar observations the following points have been established bearing upon the therapeutical applications of this remarkable substance: 1. Papayotin, when taken internally, is entirely harmless. 2. For subcutaneous injections only a sterilized solution should be employed, and this always in very small doses. 3. When thrown directly into the circulation, papayotin acts as a powerful poison by paralyzing the heart and nervous centers.

The following are the diseased conditions for which papayotin has so far been recommended: *a.* Various cutaneous eruptions, including lichen tropicus. In these affections its efficacy has not been tested by Rossbach. *b.* It has been employed to dissolve external carcinomatous tubercles. Bouchut injected it into swollen cervical glands, causing great pain and considerable fever. In three days the tumors softened, and turned into abscesses. In three cases of mammary carcinoma, and one case of scirrhus of the axillary glands, which were treated by Péan at the Hôpital St. Louis with injections of papain, the hard swellings were softened and digested. Rossbach thinks that in such complaints it is better to extirpate the morbid growths, or, if this procedure is contraindicated, he recommends injecting them several times a week with a little sterilized solution of papayotin. *c.* In diphtheria and for the resolution of croupous false membrane. Koths and Aschbach report favorable results from papayotin in fifty-three cases of diphtheria. In bad attacks of croup, Rossbach advises that a solution of papayotin, made as strong as possible, be kept in constant contact with the exudation by painting it over the latter, and also dropping it into the nose and mouth, every five minutes. *d.* Papayotin has been employed in France to assist the digestion of meat in cases of dyspepsia and other gastro-intestinal disorders. Dr. Albrecht has prescribed it successfully for various complaints of the stomach and bowels in children. Vomiting and indigestion are said to be very quickly relieved by small doses. Rossbach believes that papayotin, given by the mouth or in nutritive enemata, is especially serviceable when there is a deficiency of the normal gastric juices. *e.* Probably the solvent powers of this agent will yet be made available in many gastric carcinomata. *f.* Descourtils and Tussac report that the juice is an effectual vermicide.

SORE THROAT IN CHILDREN.—Dr. Henry Ashby has an instructive paper on this subject in the "Practitioner" for December, 1883. He begins by remarking that the importance of ascertaining the state of the fauces in a sick child can hardly be overestimated. It is not always an easy proceeding to make a thorough investigation of the throat in such cases, and, when we have succeeded in this, it must be admitted that our difficulties in diagnosis are by no means at an end. These difficulties arise in cases of febrile sore throat in their various forms, when it is not possible to decide on their simple nature or to throw them at once among the specific fevers. Is the trouble with the tonsils

an inflammatory affection merely, or is it linked with a scarlatina or a diphtheria? This is a question, unfortunately, that does not always admit of an answer, for the symptoms of scarlet fever shade away imperceptibly into a slight sore throat. It is a fact, often noted, how frequently the attendants on those sick with scarlet fever suffer from sore throat, and how often during the prevalence of an epidemic of typhoid many suffer from diarrhoea, who in no other way present symptoms of fever.

Putting aside some of the rarer forms of sore throat in children—namely, syphilitic or tuberculous ulceration, abscess, and also the congested throats seen at times in typhoid, measles, and rütheln—we may divide the more important forms into: 1. Catarrhal amygdalitis. 2. Scarlatinal amygdalitis. 3. Pseudo-diphtheritic amygdalitis. 4. Diphtheria.

1. *Simple Catarrhal Amygdalitis.*—A moderately acute attack generally begins with a feeling of chilliness or heat; there is rarely vomiting or retching; the temperature rises in the evening it may be to 103° F. The tonsils are swollen, often unequally, and congested, the mucous membrane of the soft palate is more or less injected, there is an excessive secretion of mucus, and in a few hours yellow spots make their appearance on the tonsils, the results of the secretion being retained in the crypts. The tongue becomes furred; the temperature may fall next morning to normal, to be intermittent for a few days until it finally remains normal. Such attacks are in all probability the result of several disorders and constitutional states, among which possibly cold, inhalation of sewer or foul gases, some specific poison, as that of scarlatina or diphtheria, may play a part. One thing is certain, that attacks of amygdalitis, while occurring sporadically, often occur in epidemics, sometimes one child in a school or hospital ward, at other times a number, being attacked. Simple catarrhal amygdalitis remains from first to last an affection of the mucous membrane covering the tonsils and soft palate, and does not involve the parenchyma of the tonsils, or exhibit any tendency to involve the nasal or laryngeal mucous membrane, or lead to purulent infiltration of the middle ear. There is no true ulceration of the tonsils or sloughing of the soft palate or cellulitis around the cervical glands, and in any case which has exhibited any such tendencies we may strongly suspect some specific fever. Unquestionably, such a simple attack may be the result of the poison of scarlet fever. Mild cases of the latter may occur with no rash, only a few degrees of fever, and a simple amygdalitis, and yet be followed by nephritis. Cases of undoubted scarlet fever may occur in a ward or household, to be followed by the occurrence of simple amygdalitis more or less widespread, and perfectly indistinguishable from ordinary catarrhal amygdalitis. Such epidemics of sore throat are far from uncommon; the patients should be carefully isolated, and the most rigid scrutiny employed to discover the nature of the cases, attention being especially directed to the questions of scarlatina and insanitary conditions.

2. *The Sore Throat of Scarlet Fever.*—In typical examples there is no disease so easy to diagnose as scarlet fever, but it must be said also that there is no disease that at times presents greater difficulties. The onset is sudden and abrupt, and is nearly always accompanied by vomiting, often by diarrhoea. The child appears perhaps well in the morning, goes to school, comes home feeling tired, takes its dinner, and then vomits several times; toward evening there are chilliness, sore throat, and fever, the temperature rising possibly to 104° or 105°; often the temperature never reaches so high, being not more than 100° or 101°. In weakly children the fever is apt to be of an intermittent type, the temperature touching normal, or thereabouts, the next morning, but in most cases the evening temperature is maintained next morning, or there is only a slight remission. In a well-marked case the mucous membrane of the uvula, soft palate, and tonsils is injected, having a bright red appearance; the tonsils are generally swollen equally and may nearly meet, the secretion of mucus is increased, yellow points appear on the surface, and sometimes patches of yellowish exudation are present. Frequently a semi-purulent discharge appears from the nose, and the cervical glands become enlarged and tender. The tongue is coated with a white fur of varying thickness, and cleans from the edges, displaying the well-known "strawberry tongue," in which the fungiform papillae are engorged and appear to stand out

from a smooth, bright red ground. In the more severe forms, the tonsils, uvula, and edge of the soft palate become covered with a yellowish exudation, ulceration of the tonsils ensues, their surfaces are ragged, and perforation may take place through the soft palate.

Too much care can not be bestowed in all cases of sore throat in examining the child when completely stripped, in order to detect the faintest rash. This rash does not consist in a blush or light erythema which may be present in the evening and gone before morning. The true rash is punctiform; that is, it consists of a number of fine or coarse red points, the congested hair-follicles, the intervening surface of the skin being either pale, as in patients with a faint rash, or bright red from the presence of an erythema surrounding the hair-follicles. The scarlatinal rash may thus consist of a number of bright points on a pale or on a red ground. Sometimes the rash is patchy or irregular on the limbs, thus in some respects resembling measles, this variegated appearance being produced by the presence or absence of the erythema around the congested hair-follicles. The rash appears first about the neck, but sometimes it may be detected earliest about the backs of the hands. The rash fades in a few days; sometimes, when it has only been slight, it has disappeared by the third, but oftener not till the fifth or seventh. It is nearly always followed by desquamation, but it is important to remember that in mild cases there may be no desquamation whatever, and also that children often desquamate after pneumonia, typhoid, and other febrile diseases.

The difficulties in diagnosis presented by scarlet fever principally occur when no characteristic rash is present, or when the case is seen only after the end of the first week, when no history of a rash is to be obtained, and no desquamation is present. It is important to bear in mind that at times no diagnosis is possible, that no conclusion can perhaps be arrived at as to the nature of the disease at any time during its course, and that it is necessary to carefully exclude from their fellows all patients with feverish sore throat so long as any congestion of the fauces remains.

The amygdalitis of scarlet fever is often almost, generally indeed in mild cases absolutely, indistinguishable from that of simple amygdalitis. There are the swollen, congested tonsils, the yellow spots of inspissated secretion marking the position of the crypts, the excess of mucus, the injected uvula and soft palate, and the pain in swallowing. It may not be possible to make a certain diagnosis, but any helps, however slight, are welcome. In the initial stage, the presence of vomiting and diarrhoea, a pulse of 130-160, though the temperature may not be high, marked injection of the uvula, of the edges of the pillars of the fauces, and of the tonsils will serve to render it extremely probable that the case is one of scarlet fever. In the course of a day or two, as the tongue cleans and displays the clean red surface with enlarged and congested fungiform papillae, or the nasal mucous membrane becomes involved, the cervical lymphatics enlarged and tender, or surrounded by cellulitis, or yellow exudation appears over the inner surface of the tonsils and uvula, the probability of the scarlatinal nature of the attack becomes a tolerable certainty. True ulceration of the tonsils, or a sloughing or gangrenous condition of the throat, is almost certainly due to scarlet fever, if diphtheria can be put out of the question. Sequela, such as otitis or nephritis, would be conclusive as to the nature of the attack.

3. *Pseudo-Diphtheritis*.—There is a form of sore throat, occurring both sporadically and epidemically, which has received the names of *angine couennuse*, croupous angina, and pseudo-diphtheritis, which seems to bear the same relation to true diphtheria that epidemic amygdalitis bears to scarlatina. Just as we recognize a form of feverish sore throat that passes from child to child in a ward, or family, or school, that has a striking resemblance to scarlatina but without its rash or sequela, and that appears to be due to a similar but modified form of poison, so we can recognize a sore throat, also apparently contagious, which presents many striking points of resemblance to diphtheria, and yet which we can hardly affirm is the genuine affection. This form of sore throat appears to prevail in districts especially noted for the prevalence of diphtheria, and some believe they can always connect its presence with foul smells or with sewer-gas leaking into the tenements. In its onset it resembles catarrhal amygdalitis rather than diphtheria, for it is generally sudden, and the temperature usually

rapidly rises to 103°-104°. It may be at first one-sided, afterward both sides being equally affected. The tonsils are congested and swollen, and patches of gray or grayish-yellow membranous exudation are seen on their inner surfaces; the membrane is tenacious and tough, but less so than that of true diphtheria. Membranous exudation may also be present on the uvula and soft palate. The attacks, though closely resembling true diphtheria—so much so that in some cases the diagnosis may be impossible—yet differ from it in that the cervical glands are rarely affected, the membrane is less tough and the injection of the mucous membrane less, the nasal mucous membrane is unaffected, there is no albumin in the urine, and the attack is not followed by the usual sequelae. The constitutional symptoms are less marked by depression of the whole system. Such attacks are often spoken of as diphtheritic sore throats, and are prone to affect both children and young adults; the prognosis is good, and in a week, more or less, the patient is convalescent.

4. *Diphtheria*.—The characteristic appearances in pharyngeal diphtheria are well known. The attack is for the most part insidious, and, unlike scarlet fever, there is no sudden onset of fever. Sore throat or difficulty of swallowing is complained of, or perhaps a foetid discharge from the nose, or swelling of the cervical glands, with cellulitis, first calls attention to the case. Probably at the first examination the white or gray patches of exudation will be seen on the uvula, the edge of the soft palate, or the tonsils, while the mucous membrane around is intensely injected. The membrane is raised, not readily separating from the mucous membrane beneath, and, if separated, leaves a bleeding raw surface; there is often much excess of mucoid secretion, the nasal mucous membrane becomes involved, and a sanious discharge from the nose takes place. The temperature is not often high, being as a rule not higher than 100°-102°, the pulse is weak, the face is pallid, the urine is loaded with albumin or, less often, with blood. The only diseases with which pharyngeal diphtheria is likely to be confounded are, in the mild cases, pseudo-diphtheritis and, in the severer forms, malignant scarlatina *sine eruptione*. In the latter case a difficulty may occur when in malignant scarlet fever membranous exudation forms on the throat, the nasal membrane, or the conjunctiva, especially if such a case is not seen from the first and no history of a rash is to be obtained. A difficulty does not often arise in the diagnosis. In scarlet-fever throats true membrane is rare, the tonsils may be covered with yellow exudation, sloughing and perforation of the palate and much external cellulitis may take place, but there is an absence of the leathery whitish exudation adhering firmly to the mucous membrane so characteristic of true diphtheria. There may be albumin in the urine in scarlet fever, but it will be only slight in amount, while in diphtheria there is usually one half or two thirds.

"It is an interesting question," Dr. Ashby observes, in conclusion, "that does not admit of a certain answer. In what relation does epidemic tonsillitis stand to scarlet fever, or diphtheritic sore throat to diphtheria; are the poisons alike and yet essentially different, holding a relationship like that of variella to variola, röteln to measles, summer diarrhoea to Asiatic cholera? Are these sore throats in reality the result of infection with attenuated scarlatinal or diphtherial poison? The remarkable results obtained by Pasteur in the cultivation of the organisms concerned in chicken-cholera and splenic fever are extremely suggestive, and may help to explain how at one time, or in one district, cases are extremely severe, and at another time or place the only effect produced consists in a series of feverish sore throats. Do such attacks of sore throat protect from scarlet fever? Long-continued and collective investigation alone can afford an answer."

THE BITE OF AN EPILEPTIC.—In commenting on a case of alleged death from the bite of an epileptic, the "Lancet" (January 12, 1884) says: There is no poison in the bite of a person in a fit, as there is in the bite of a rabid dog. It is, of course, desirable that every care should be taken to avoid the bite of an epileptic, as it is also that of any other excited or enraged creature; but there is not the slightest ground for supposing that worse consequences will follow an injury of this class than one of any other description, if it be equally severe and is attended on the part of the victim by a morbid state of the constitution.

Lectures and Addresses.

THE CARTWRIGHT LECTURES

ON

METHODS OF STUDYING THE BRAIN,
DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COL-
LEGE OF PHYSICIANS AND SURGEONS, NEW YORK,
FEBRUARY 2, 4, AND 6, 1884.

By BURT G. WILDER, M. D.,

PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN COR-
NELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF
MAINE.

LECTURE II.

*Methods of Manipulation: Removing, Preserving, and Ex-
amining the Brain.*

(Concluded from page 209.)

THE method last described (continuous arterial alinjection*) brings the preservative liquid most abundantly to the parts covered by the vascular pia, and is thus best adapted for the study of the ectal features of the brain, the base, the arrangement of the fissures and gyri, and the contour and proportions of the organ. With fetal brains, where the parietes are thin and the entocœlian plexuses very large, this method may suffice for the due preservation of the en-

FIG. 44.—THE LEFT POSTCORNU EXPOSED FROM THE LATERAL ASPECT; $\times 1$. Drawn by Mrs. Gage. The brain was that of an adult male; the cœlia were alinjected from a medicornu; the occipital lobe was cut off so as to include a little of the splenium, and the postcornu exposed by a dorso-central section, and subsequent removal of small portions by limited sections in oblique planes. The calcar ("hippocampus minor") is large and well defined; at its caudal end the cornu narrows suddenly and terminates at a point just ventrad of the letter *t* in the word *postcornu*. Ventrad of the calcar is the triangular *Eminentia collateralis*, the cephalic boundary of which is the hypocampa ("hippocampus major"), only part of which is included in the preparation. Dorso-cephalic of the calcar is a smaller but perfectly distinct elevation, which evidently includes fibers of the splenium, and will be mentioned in Lecture III.

tire mass; but with the adult human brain, if the special object be the determination of the form, extent, and con-

nections of the cavities and the contour of their walls, arterial alinjection should be replaced by or combined with the *continuous injection of alcohol into the cœlia themselves*.

Continuous Cœlian Alinjection.—The repeated injection of alcohol into the cœlia is recommended in "Anatomical Technology," p. 435; the feature of *continuity* was introduced in December, 1882, first in the preparation of hearts, and soon afterward for the brain. Its advantages are as follows:

1. It facilitates the preservation of the entire brain.
2. It insures the preservation of the immediate cœlian parietes, and their contour is thus retained (Fig. 44).
3. The apposed surfaces are kept apart, so that there need be no doubt as to the cœlian limits.
4. When either of the parietes is removed, the cœlia appears as a distinct excavation, and not merely a slight depression.
5. In transection, the cœlian lumen is clearly defined (Fig. 45).

FIG. 45.—CEPHALIC ASPECT OF A TRANSECTION OF THE RIGHT OCCIPITAL LOBE; $\times 1$. Drawn by Mrs. Gage. This represents part of the same brain as Fig. 44; it shows not only that alinjection of the cœlia insures the preservation of the parietes and their separation from each other, but also, by comparison with Fig. 44, the lack of symmetry of the cornua and the calcarina.

The continuity of the flow is provided for by the connection of the cannula through a rubber tube with a reservoir of alcohol; but no considerable pressure is exerted, both because the cavities would be abnormally enlarged and because there might be caused a rupture of the parietes.*

Instead, therefore, of being tied into a vessel, the cannula hangs freely at the end of a straight rubber tube, and near its tip is adjusted a collar made by perforating a disc of sheet rubber,† which prevents its undue penetration into the cœlia. The alcohol displaces any air which may be in the cœlia, and its own overflow occurs at the place of entrance, or at any other orifice, natural or artificial, which may exist. The filling of the cœlia is indicated by the swelling of the whole brain, especially the tips of the tem-

* Notwithstanding the softness of encephalic tissue, its ability to withstand an unexpected degree of pressure is evidenced by the rarity (if, indeed, they ever occur) of ruptures of certain very thin portions of the parietes (*terma*, etc.), and by the fact that alcohol injected into the diacele of a cat by means of a syringe has escaped from the *Caudalis centralis* of the myelon as a stream 8 to 10 cm. long, although the orifice of exit was 42 mm. from the tip of the metacele and 66 from the place of injection.

† Suggested by Professor Gage.

* Injection of alcohol.

poral lobes; if these or other parts have been removed so as to permit the too free escape of the alcohol, the orifices may be more or less completely closed by pledgets of cotton, or by glass plates supported against a smooth cut surface of the brain.

The place of injection varies according to the nature of the preparation desired. When the entire cavity is to be filled, or when the boundaries of the *aula*, etc., are to be studied, the cannula is conveniently inserted into the orifice left by the removal of the hypophysis.* The cannula may even be tied into the *infundibulum*, but this measure is of doubtful utility. If there are reasons for not mutilating the mesal part of the base of the brain, the tip or side of a temporal lobe may be cut off and the cannula inserted into the *medicornu*; or a *postcornu* may be reached in like manner; the tubular *mesocele* ("iter") forms an admirable orifice for the reception of the cannula, and, if the brain be transected at the *mesen*, either division may be alinjected separate.

During alinjection the brain should be supported in such a way as to occasion the least possible pressure. If it can be kept within the cranium, only the base may be exposed, or whatever other region may be selected. If the *cœlian* parietes alone are to be studied, the dorsal region of the skull and the brain may be sawn off to within 1 to 2 cm., of the *callosum*, and the exposed surface supported upon a glass plate; in like manner considerable masses may be removed from the frontal region. Finally, since *cœlian* orifices are easily closed so as not to prevent the success of the injection, the lateral masses of the hemispheres may be removed to within 3 to 4 cm. of the *meson*, and the occipital low *cerebellum*, etc., all separated by a transection through the *mesen*, leaving the most complex and difficult region of the brain comprised within a block 5 to 7 cm. in diameter.

When the entire brain is to be prepared by alinjection into both the arteries and the *cœlie*, the former are washed out with warm water or normal salt solution (water, 2,000; sodium chloride, 15), or a ten-per-cent. solution of chloral hydrate, while it is still in the saturated brine in which it was placed after extraction. The alinjection cannula is then secured in the basilar artery, and the cut ends of other arteries are tied. A towel or other piece of porous cloth is passed under the brain, and the latter thus transferred to a vessel of 50-per-cent. alcohol; the ends of the towel are secured at the edge of the vessel so as to support the brain in its hollow at a proper level, the base being just above the surface of the liquid. In the absence of a metal vessel constructed for the purpose, a common wooden pail may be used, or a metal pail may be pushed through the rim of a wooden one. The flexible (copper or lead) wires for supporting the cannula and tubes may be set in holes in the wood, or in appropriate sockets attached to the metal. The cannula or tube may be merely pinched by doubling

the end of the wire, or more neatly and conveniently secured by means of a small clothes-pin or "garment-clasp" attached to the end of the wire. In all cases, the cannula and its tube should be supported by separate wires, so that the movement of the latter may not affect the former.

The flow of alcohol is regulated by "pinch-cocks"; it is naturally more free through the *cœlie* than through the vessels, and in either case the overflow must be provided for. There should be a faucet near the bottom of the vessel and another near the top, a rubber tube leading from each into a receptacle holding at least as much as the reservoir of alcohol; in the mouth of the receptacle is set a funnel with a fine cloth to exclude particles which might clog the cannulae or the vessels. The ordinary overflow escapes by the upper faucet, but, when some adjustment or examination is required, the lower one is opened until the parts are exposed. The vessel may be covered with two semicircles of glass, or a circle may have a slot cut from one side to permit the passage of the tubes.

A brain preserved by one or more of the methods above described not only retains its natural shape and cavities, but is so firm of texture that it may be handled freely and carried like *stearin*. How much more available it is than a fresh brain for elementary study and for permanent macroscopic preparation can hardly be realized without actual experience. Each year, in our great cities, scores of human brains fail of their greatest usefulness or are altogether lost for lack of timely and systematic preservative measures; each year, likewise, scores of young doctors are graduated without the practical knowledge of the brain which they ought to have. All over the country, too, are curators of museums, physicians, and teachers who would greatly prize a human brain for exhibition or study. The skillful and public-spirited anatomist who will supply this legitimate demand, and utilize this wasted material, will at least be entitled to the gratitude of all who may be directly or indirectly benefited by his enterprise.

The brains of cats and other small animals are more easily cared for than that of man. Ordinarily, they should be left in a part of the cranium, and the edge of this may be clamped to the end of a wire, or the whole supported in a wire cage or a cup of sheet-lead or block-tin.

Amphibian brains should always retain a part of the skull, which may be securely held by means of the "garment-clasp" already mentioned. Since the delicate tissue will not resist even the weight of the cannula, the latter is secured at a little distance from the brain, and the alcohol permitted to flow at the orifice. The best results from alinjection of the amphibian brain as a whole are when the alcohol is admitted through an orifice in either hemisphere;* but, if both hemispheres are to be kept uninjured, the *metatela* may be partly detached. Strong alcohol may be used at the outset, but the brain must be first soaked in water or "normal salt solution" for 15 to 20 minutes to prevent adherence of the pia.

Solid Injections of the Cœlie.—The advantages of a

* No name seems to have been given to this very distinct feature of the base of most brains. The descriptive term *Foramen infundibuli*, which was suggested by me in 1881 (9), and is employed in "Anatomical Technology," becomes, like *alcohol injection*, burdensome when used many times in a day, and I propose to replace it by the single short word *lura*, which in Latin signifies a leathern bottle or the mouth thereof.

* Brains of amphibia (*Necturus*, *Cryptobranchus*, and *Rana*) thus prepared were shown at the meeting of the Society of Naturalists of the Eastern United States, December 28, 1883.

solid cast for studying the form of an irregular cavity are so great and so obvious that the rarity of such preparations is only to be explained by the prevalent neglect of all cœlian matters, which was referred to in the first lecture. In 1878 Welcker (1) published figures of wax casts of the human cœlia; prior, however, to my acquaintance with that paper, plaster casts of portions of the cœlia of the cat and sheep had been made and figured in "Anatomical Technology," pp. 435, 458. More recently the cœlia of the cat have been injected with the three following mixtures:

1. Plaster of Paris and gelatin, equal parts.
2. Paraffin colored with orange chrome, melting point, 45° C.

3. "Base-plate" material (wax and gutta-percha) used by dentists, with a slight addition of gutta-percha and rubber in benzine, and of paraffin to lower the melting point.

All of these made good casts, the last named being the toughest, and therefore most satisfactory.

An adult human brain was also injected *per luvam* with mass No. 3. All the cornua were partially filled, but at their tips there was evidence of the presence of air or liquid, and the force required to carry the mass through the medicornua to a level higher than the place of injection ruptured the attachments of the diatela and so permitted the mixture of the contents of the cœlia and of the diacela. Better results will doubtless be attained by first hardening the cœlian parietes by injection and dividing the brain into several pieces, so as to deal with the cornua independently; if such a division were not made, the cord would inevitably break at the portæ and in the mesocele.

Removal of the Brains of Young Subjects and Small Animals.—The saw is rarely appropriate, excepting when the entire head is to be hemisected. The instruments to be used are nippers, coarse, curved scissors, the trephine, and the dental engine. Of these, the most useful are the nippers, the "diagonal, side-cutting nippers" of the dealers in hardware.*

Notwithstanding their name, the nippers are perhaps more useful for breaking than for cutting the skull in exposing the brain; all pulling upon the dura must be avoided, and the scissors may be employed for dividing the dura or thin portions of the bone. With children one or more years old, parts of the cranial bones are too thick for the nippers, and may be penetrated by the trephine. The little marmoset exhibited at the lecture had its brain exposed by means of a bur and small circular saw operated by the "dental engine," and it is obvious that this instrument is well adapted for manipulations upon small animals and fetuses, especially when the brain is to be exposed while fresh, so that

any pressure or traction may do harm; by it also the calva may be detached in two pieces, as already described, for the adult, and, finally, the base of the skull may be removed piecemeal, either for ordinary exposure of the brain or in the isolation of the roots of the cranial nerves.*

After what has been said of supporting the adult brain in brine during the process of removal, it is only necessary to add that this measure is even more essential with fetuses of children; the entire body should be, if possible, placed upon a cloth in a vessel of the brine, the head being steadied upon a bed of cotton or held by an assistant.

Dissection of the Brain.—From the practical standpoint, encephalic anatomy contrasts strongly with the anatomy of the rest of the body. With the latter, dissection is universal, and sections are seldom made; with the former, sections, microscopic or macroscopic, are the rule, and dissection almost unknown. The difference is due to the "nature of things," just as is the preponderance of osteology over neurology, but, like many other natural conditions, it may need modification.

The advantages of sections for surgical, pathological, and regional study are obvious; they are easily made, even with the fresh adult human brain, especially by means of the apparatus devised by Professor Dalton.† If the human brain were like that of a frog or *Necturus*, or even an opossum, with the several segments of approximately equal size, and nearly upon the same plane, the common method would be more appropriate for macroscopic study. But, in view of the extreme cephalic flexure and the overlapping of certain segments by others, the objections to sections are as follows:

1. They present plane surfaces which do not naturally exist in the brain.
2. They are almost invariably oblique with respect to the cœlian axis.
3. They always include more than one encephalic segment, and are therefore, so far as the beginner is concerned, apt to be more confusing than instructive.‡

The foregoing apply to all sections. A macroscopic section, especially of a brain which has had the cœliae aligned, presents the advantage of exhibiting in perspective enough of the natural contours of parts to facilitate their recognition and comparison.

Admitting, then, that sections have their uses, what I urge is, not that section-making be practiced less, but dissection more.

The methods of dissecting the brain taught in the Anatomical Laboratory of Cornell University* may be indicated briefly as follows:

* The dental engine is also useful for drilling bones in the mounting of skeletons, and for experimentation upon the brain.

† "Medical Record," February 15, 1879, July 31, 1880.

‡ The following vigorous expressions refer directly to horizontal section: "It is unfortunate indeed that candidates for the medical diploma are still very generally required to describe the appearances presented by the brain dissected, or rather destroyed, by the old method of slicing—a method most unphilosophical in its conception, and totally inadequate to impart any real information in regard to the structure of the brain."—Solly, p. 12.

* In addition to a somewhat extended account of encephalic structure and development in the general courses of lectures upon physiology and vertebrate zoölogy, a special course is given upon the brain.

* "Anatomical Technology," Figs. 10, 11. Seven sizes are made, ranging in length from 10 to 20 cm. (4 to 8 inches). The largest will cut any bone of a cat, or of a child under three years of age, but the medium-sized (15 cm.) answers for most purposes, and the smallest only can be safely employed in exposing the brains of amphibia. The handles of the smallest nippers should be lengthened so as to be more readily grasped, and, for the finest work, the points of the blades should be sharpened. The English (Stubbs') nippers are more highly tempered and better finished than the German, and also more expensive, but none of them cost as much as the surgical "bone-forceps" or the dental "wedge-cutters," the only advantage of which is the spring.

1. The art of dissection is acquired upon the brains of common mammals.

2. Alcoholic brains are dissected before fresh ones.

3. The normal macroscopic structure of the organ is carefully studied before the microscope is used or pathological specimens examined.

4. In addition to sections with large knives, *dissections* are made with small scalpels, and cavities are explored with blunt points and blow-pipes.

5. Delicacy of manipulation is insisted upon.

Let us examine into the soundness of these methods.

1. Aside from facilitating the comprehension of encephalic morphology (Lecture I, p. 147) and imparting manual dexterity (which will be referred to farther on, and might be acquired in the carving of any material of like consistence), the value of preliminary dissection of the brains of common mammals depends upon the correctness of the three following propositions: (1) The human brain, even under the most favorable conditions, is more or less difficult to obtain, preserve, and dissect. (2) The most real and lasting kind of knowledge is that which is obtained, not from descriptions, or plates, or even models, but from *actual handling and inspection of the thing itself*. (3) Notwithstanding man's obvious physical peculiarities, his reputed mental and moral distinctions, and his presumed unique destiny, the human brain contains few, if any, parts visible to the unaided eye which are not represented in the brain of some other mammal.*

As compared, therefore, with the study of descriptions or plates of the human brain, the actual brains of cats, dogs, rabbits, monkeys, sheep, etc., may be examined in the expectation of learning the forms, connections, and relative positions of parts, and, neither last nor least, their *names*; in short, everything save the comparatively few differential human peculiarities, with all the reality and distinctness which attend any kind of "object-teaching." In the effort to ascertain the structure of the far-off Australian "Dingo," we should certainly familiarize ourselves first with so much of canine anatomy as might be learned by dissecting dogs nearer home.

Were the human brain absolutely inaccessible for dissection, as it is for experimentation, the anatomist would be forced to follow the example of the physiologist and gain all his encephalic information from animals. In view of the inconvenience and expense—nay, too often, the impossibility—of procuring fresh or well-preserved human brains, to permit their dissection by beginners is, as I said five years ago,† as if journeymen carpenters and tailors were to learn their trades upon rosewood and cloth of gold. "*Fiat experimentum in corpore vili.*"‡

* Let him who imagines that between the bodies of men and brutes is fixed a gulf, great and impassable, revert to the representations of the brain in amphibia and in human and feline embryos (Figs. 1, 6, 11, 12, 13), and carefully compare with the base, meson, and other regions of the human brain the corresponding parts of a cat or monkey.

† "The Anatomical Uses of the Cat." "N. Y. Medical Journal," October, 1879.

‡ Among the few anthropotomical authors who seem to have recognized distinctly the application of this aphorism to anatomy was Solly: "I have been thus minute in my description of the brain of the rabbit,

The smaller size of animal brains constitutes an objection to their preliminary dissection which is more apparent than real, and is, indeed, almost a "blessing in disguise." Since there is practically no limit to the number of animal brains which each student may dissect, the mistakes or oversights with one specimen may be corrected upon others; moreover, as was foreseen by Cuvier in advising a student who claimed to have found something new in human anatomy to anatomize an insect and then re-examine his supposed discovery, whoever has successfully dissected the brain of the cat will find no difficulty with that of man.

2. The second rule is based upon three practical considerations: (1) Of the visible features of encephalic parts, *form, relative position, and connection* are distinctly morphological, while *color*, like histological composition, has a physiological significance. (2) The fresh brain is less easy to cut, and requires constant support, whereas the alcoholic may be held in any position and carved like cheese. (3) The beginner should advance cautiously, and therefore slowly, and the medical student is especially liable to interruption. The fresh brain remains fresh but a very short time, while the alcoholic is in itself imperishable. Leisure means not only more careful dissection, but also the taking of notes and the making of drawings; hence all the arguments which I have advanced* in favor of preliminary anatomical work upon a small animal, which may be kept in alcohol for an indefinite time at slight expense, apply to all alcoholic brains in general, and to those of cats and other animals of moderate size in particular.

After repeated dissection of alcoholic preparations, the anatomist is better qualified to manipulate the fresh brain and to appreciate its beauty. I use the last word advisedly, for, however unattractive may be those "subjects" and pathological "cases," the most exacting artistic sense can hardly fail of satisfaction with the soft white and gray and pink of the newly extracted brain. Resting securely in its calva, for him who has been disciplined by prolonged experience with the "pickled" organ, there are few more attractive, stimulating, or nourishing articles of intellectual pabulum than a fresh brain "upon the half shell."

3. This rule is in strict accordance with common sense, and with custom in most branches of learning. Its two divisions have been separately enunciated by writers who certainly were not ignorant whereof they spoke.† Whether because this animal is always easily to be procured, and because I am sure that whoever will take the trouble to go over this dissection once or twice before attempting that of the human brain, will find his path much facilitated by the knowledge and the manual dexterity he will have acquired."

* "The Anatomical Uses of the Cat." "N. Y. Medical Journal," October, 1879.

† "I beg of you not to employ the microscope until you have, to a certain extent, mastered the details of descriptive anatomy. As soon would the astronomer place the telescope in the hands of his pupil . . . as would the judicious teacher of anatomy suggest the examination of objects by the microscope before strict ideas of form and relation had been acquired by the study of the visible parts."—Goossens.

"In all departments of investigation it is right to commence with the study of that which is common, simple [normal], and regular, and thence to proceed to inquire respecting that which is unusual [abnormal] and irregular."—BUCKNELL and TUCKER, "Manual of Psychological Medicine."

or not, in some cases, the authors of histological papers are altogether clear respecting the position and relations of the parts concerned, the systematic observance of this rule would at least reduce the number of readers of such contributions who neither appreciate their excellences nor recognize their defects from a lack of adequate familiarity with the gross anatomy of the brain.

The objections to the primary employment of the microscope do not apply to the use of a simple lens like the "tripod magnifier" or "linen tester," which assists the eye to see more plainly that which is already visible, but introduces neither optical nor histological complications.

4. Large knives are useful in making sections, and in reducing the brain so as to permit ready access to the region to be examined. But it is to be noted that, excepting at the meson, the encephalic parts are never bounded by plane surfaces, or by straight lines, so that the natural contours are more easily and successfully exposed by means of narrow-bladed scalpels and probe-pointed instruments. The so-called "Charrière" scalpel answers the purpose generally, but sometimes, especially with fetuses and small animals, eye-knives with still narrower blades are required. In the exploration of cœlix and the determination of the relations of membranes and plexuses, the dissection is accomplished less by cutting than by "poking" and "blowing," for which the syringotome, or tracer, and the flexible blow-pipe,* are indispensable. Whoever once employs the first-named instrument upon the brain will never willingly be without it. The length and flexibility of the blow-pipe enable one to blow in any direction, and to hold the object at a distance convenient for observing the effect of the inflation. So instructive indeed is this mode of temporary injection that one of Oliver Wendell Holmes's "Aphorisms for Dissections" may be extended to read: "Let the eye go before the hand, the mind before the eye, and the breath before the mind."

This rule is aimed at all forms of anatomical Philistinism. Hyrtl complains (p. 62) that "some people hold the forceps like fire-tongs, and the scalpel like a cheese-knife." One of the most common and pernicious habits of the anatomical beginner—who is a Philistine only when he makes no effort to reform—is that of aimlessly pinching and poking his specimens, especially when showing them to others. This *poking* may be most aptly compared with the dabbling which hens inflict upon a piece of meat. The anatomist should exercise constant self-control, restrain what Hyrtl calls the "*Furor secundi*," and never touch his specimen except for a good and sufficient reason. From the ecclesiastical standpoint, perhaps, the "laying on of hands" can not be overdone, but in practical anatomy its excess is likely to

prove the reverse of a blessing. These cautions are called for in respect to the dissection of muscles, etc., to which the examination of the brain is as watchmaking to the wielding of hammer and tongs.

THE GEOGRAPHICAL DISTRIBUTION

OF

URINARY CALCULUS,

WITH AN INQUIRY INTO ITS CAUSE.*

By EDWARD L. KEYES, M.D.,

PROFESSOR OF CUTANEOUS AND GENITO-URINARY DISEASES IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

It is a fact universally recognized that stone occurs much more frequently in certain portions of the world than in others, but a satisfactory explanation of the fact has not yet been established. It is customary to ascribe it to the hard waters of the affected districts, but investigation disproves the validity of such a claim. Agnew† states that in certain valleys in Lancaster County, Pa., of limestone formation, the water is very hard, being strongly impregnated with lime, yet calculus is not common in these valleys, and he joins former writers in the very apposite reflection that it is difficult to understand how calculi, most of which are composed of uric acid, should be stimulated into growth by the use of alkaline lime-water.

Civiale, whose statistical researches on this subject were very thorough, has written:‡ "Dr. Warren, of Boston, recently told me that stone is very rare in Massachusetts, and is almost unknown in those localities where granite rock abounds, while it is found occasionally at other points where the soil is calcareous. But this alleged influence of the nature of the soil upon the production of calculous disorder is an hypothesis only admitted to explain facts the true cause of which is not evident. Several of the localities from which I have received statistical documents possess the granite formation, yet, in spite of this, calculus is far from being a rare disorder there. I may cite among others certain points in Sweden."

Again, speaking of the stone cases reported from the department of Var in France, he says: "The malady seems to be equally divided among all classes of society; the nature of the soil, which is flinty and granite on the coast and calcareous in the interior, does not appear to make any sensible difference in the distribution of the cases."

Cadge,§ of Norwich, England, on the other hand, ascribes the great frequency of calculous (uric acid) disorder in that district to the hardness of the waters. Prout distinctly states his belief that hard waters are a factor in the production of stone, and many excellent urinary pathologists and practical surgeons agree in this way of thinking. Reginald Harrison|| tries to explain it on the ground that hard waters interfere with digestion, and in that way

* These instruments are figured and described in "Anatomical Technology," pp. 64, 66, 71. The syringotome is a small, curved, blunt-pointed bistoury, sometimes called "canaliculus knife." The tracer—a much cheaper instrument, made at my request by Messrs. Codman & Shurtleff, of Boston, Mass.—serves an admirable purpose in ordinary dissecting (especially in isolating nerves and vessels), and in experimentation where there is danger in using the scalpel, but for work upon the brain is far inferior to the syringotome. The attachment of a rubber tube 30 to 40 cm. long to either half of an ordinary metal blow-pipe was first, so far as I know, suggested by a former student, Mr. C. F. Clark.

* Read before the New York Surgical Society, February 12, 1884.

† "Surgery," vol. ii, p. 631.

‡ "Affection calculeuse," Paris, 1838, p. 588.

§ "Trans. of the Brit. Med. Assoc.," 1874.

|| "Lectures on the Surgical Disorders of the Urinary Organs," second ed., 1880, p. 246.

modify the conditions of the solids in the urine and the state of the colloids. He adduces in support of his argument the frequency of stone in the bladder in the young among the poor about Norwich, and the fact that milk is scarce and dear, and quotes from the essay of Cadge that the frequency in this district of the occurrence of stone in children "will be found in strict accordance with the difficulty of procuring milk."

In this connection, as to the liability of drinking-water to stand in a causal relation to calculous disorder, it is proper to call to mind a fact vouched for by Roberts,* and only to be explained on the ground of coincidence or of cause and effect. He says: "The suburban district of Hulme supplies considerably fewer cases of stone to the Manchester Infirmary since the pipe-water has replaced the old pump-water supply."

It is proper also to refer to a curious indirect means by which the drinking of water may prove a source of stone formation. Zancarol,† surgeon to the Greek Hospital at Alexandria, Egypt, states that the natives drink unfiltered Nile water and imbibe the *Distoma hematobium*. That the animal and its ova can always be found in the urine and among the layers of stone extracted from the natives, and that the latter suffer frequently from calculous disorder. Foreigners, on the other hand, who drink only filtered Nile water, do not often have stone, and their urine does not contain the distoma or its ova.

Roberts‡ also ascribes the frequency of calculus in Egypt to the presence of the minute urinary parasite, the *Bilharzia hematobia*.

But to return to the water question pure and simple. Mastin* takes the other side of the argument, showing that in Kentucky and Tennessee sandstone districts, where the water is very soft, calculous disorders are common, while they are just as frequently encountered in the limestone areas of the same region, where hard water is drunk. In Alabama, where stone is quite uncommon, Mastin says there have been only fifty to seventy-five operations performed upon the natives of that State since its settlement in 1817; most of the cases have originated in a belt of country running east and west, and including Tuscaloosa, "a pure sandstone region, with the softest and best water in the State." Mastin further adds, in connection with the question of stone in Alabama: "The northern and eastern sections abound in blue limestone, and the water is very strongly impregnated, yet we rarely, if ever, hear of a case of gravel or limestone within these limits. Again, in middle and southern Alabama the base of the soil is what is known as 'rotten limestone,' and the water strongly alkaline; this is also the case in eastern Mississippi, and still we have been unable to obtain reliable information of even a half-dozen cases of stone having ever occurred in these regions."

He cites also Dr. Guild, the leading surgeon of Tuscaloosa, as asserting that all his stone cases have come from the sandstone district where soft water is used.

Therefore it seems fair to assume that whatever influence hard water may have in the production of stone must be exercised in some secondary manner, as by deranging the digestion—if it operates at all—which may be considered doubtful.

Probably no country is entirely free from areas in which stone formation is relatively prevalent, but the distribution of these areas seems to be arbitrary. Thus, in England, where stone is quite common, the eastern counties of Norfolk and Suffolk appear to be most afflicted. It is noteworthy that as many cases occur each year in Norfolk, among its 438,656 inhabitants (Cadge), as in all Ireland, with a population of 5,412,377. The northern counties of Ireland and of Scotland furnish more cases than the remaining portions of those countries.

Calculous disease abounds in France, as Civiale has clearly brought out, in Teneriffe, in Iceland, in Egypt. It is also very common in Russia, especially in the central parts of European Russia. Klein* states that cases of stone sometimes constitute a fifth of all the patients under treatment in the hospitals of Moscow.

Estlander,† on the other hand, shows that primary calculous disorders are almost unknown in Finland, the University Hospital case-books containing the case of only one Finlander with stone originating in the kidney during a period of forty-four years. There were cases of phosphatic stone with paralyzed bladders, etc. Civiale‡ notices a similar immunity in Christiania, where, out of 3,211 patients in hospital during four years, only one had stone; while in the hospital of Gothenburg, in Sweden, an establishment of sixty beds, there had been no stone case since the founding of the institution, a period of fifty years.

Fayrer,* a well-known authority upon medical questions in India, states that stone is very frequently encountered in the northwestern and central provinces of that country; 554 patients were cut for stone during a single six months in 1863. In Lower Bengal stone is rare. Fayrer|| says that lithotomy had been performed only about one hundred times in the Medical College Hospital up to 1873. Harris confirms the fact as to Bengal, and ascribes the prevalence of the malady in the northwestern provinces to the cold winds which blow from the Himalayas and to a heavy unfermented bread used by the natives. Dr. Garden's testimony^A from the Sarahunpore Dispensary is corroborative of the frequency of stone in India. Mastin◇ refers to Curran for authority in stating that Hindostan is exceptionally rich in stone cases. Vandyke Carter‡ speaks for Bombay and the great prevalence of oxalate-of-lime calculi in that region. He thinks that stone is more common in Bombay or West-

ern India than in the Southern or Madras Presidency. Mr. Dudgeon,* of Pekin, who succeeded Kerr in China, informs us that in China, at Canton, and Takow in Formosa, calculus is found, but apparently not elsewhere. At Pekin the water is full of lime, at Canton very soft. Kerr† also states that Canton furnishes the stone cases of China, the missionary hospitals of twenty years' existence in Ning-po and Shanghai and at Pekin and Hangkow for eight years having supplied attendance to thousands of patients, but not to a single case of stone. The Rev. P. Parker, it appears, founder of the Medical Missionary Society, performed the first lithotomy of which there is any modern record in China.

In Norway, Sweden, Denmark, Styria, and Spain stone is not very common.

In France and Holland it is abundant; in Austria, Germany, Italy, Persia, and Syria it is reasonably frequent in occurrence.

In Mexico, Central and South America, and Australia, so far as known, the disease is not common. Livingstone failed to find syphilis or stone among the natives of Central Africa.

In North America—in the United States—the greatest number of stone cases originate in the central districts—Tennessee, Kentucky, Ohio, Indiana, Missouri, western Pennsylvania, Virginia. In Utah it is said to be common. Authorities differ as to Georgia and North Carolina. In the Northern, Eastern, Gulf, Southern, and Western States calculus is uncommon, as it is also in the Canadas and British Possessions.

These irregularities of distribution are not satisfactorily accounted for by any peculiarities of race, food, habits, soil, climate, temperature, or water.

I am speaking of primary acid stone formation. Secondary phosphatic stone, due to obstructive and catarrhal maladies of the genito-urinary tract, or to the presence of a foreign body, are found equally in all climates and in all conditions of life, provided only the proper ætiological factors are present locally in the individual.

Why, then, does the fact exist that certain portions of the earth's surface are more fertile in stone cases than other portions.

Race may have something to do with it, even under the same conditions of climate, etc. Gross,‡ among the lithotomies reported during a certain period in different Southern States of mixed population, found the proportion to be one negro to six whites. Rayer states that the negro escapes in Egypt while the Arab suffers. Mastin* has collected 3,039 reliable lithotomies in America, and finds only 102 put down to the negro, 31 to the mulatto. Mastin further notices that gout is very rare among the black people in the United States, and he quotes Winterbottom as vouching for the same fact for the native Africans around Sierra Leone. These statements appear to have a direct bearing upon the question. Reports like those of Livingstone concerning the negroes of Central Africa are not in point, since

the districts did not contain a population of mixed races for comparison.

Climate.—That climate alone should influence stone formation seems improbable. There is no striking analogy of climate between Moscow and Kentucky. Temperate zones seem to be most afflicted, yet the cold winds of the Himalayas and the general boisterousness of the winds about Norwich, England, have been accused of contributing to the stone tendencies of those regions. The central districts of the United States, however, are not pre-eminently windy. In France, Civiale found the proportion of cases in the Var district the same inland and on the coast. The New England shores are subject to dampness and boisterous north-easterly gales, yet the calculous malady is not common there. Soldiers and sailors are reported by all who have given attention to their statistics to be remarkably free from stone, yet their life is surely one of exposure, and the reason for their immunity must rather be set down to the fact that most men practicing these professions are between the ages of twenty and forty—a period of life most exempt from stone.

Social condition, habits, and occupation are not paramount as ætiological factors of stone, although they have a certain bearing upon it. Civiale distinctly states that in his collections in France social position made no difference in the relative number of cases found in a certain district. Undoubtedly there are more stone cases among the poor than among the wealthy, but the latter class is very small in any community, and nearly all the cases of the poor go to hospitals for operation, where they are sure to be recorded, while the wealthy escape tabulation to a certain extent.

In New York there is very little tendency to stone formation. During nearly thirteen years' connection with active surgical work in the Bellevue and Charity Hospitals, I have found in my service only two cases of stone. All the others with which I have had to do in hospital have been sent in by myself from outside. By far the greater portion of stone cases which I have had to do with have been found among patients in easy circumstances, but this, of course, is accidental, and by no means indicates that more wealthy than poor people have stone in New York.

Thompson,* however, remarks that he does not "know any disease which marks more distinctly or more curiously its relations with class than this. So common is stone in the children of the poor, comparatively speaking, that at Guy's Hospital, surrounded as it is by a very large neighborhood, densely populated by some of the worst-nourished classes of the community, quite one half of the cases admitted are children. Among the same classes, however, it is rare at the other end of life, very few elderly workmen in London being afflicted with it. On the other hand, among the well-to-do and well-fed, while almost never found in childhood, it is comparatively common in advanced age."

Alcohol.—It is doubtful whether alcohol will produce stone without other predisposing agencies. In large cities alcohol is consumed freely, but no statistician has noted a special

prevalence of stone among adult dwellers in cities over the relative average among the natives in the surrounding counties. An abundance of liquor is consumed in Scotland and in Ireland, doubtless as much as or more than in England, yet the latter locality is the favorite one for stone. Some wines, like the Rhine wines, as Soemmerring has pointed out, being charged with bitartrate of potash, rather militate against tendencies to stone, but sweet, fermented wines, champagnes, and malt liquors, since they increase the tendencies toward uric-acid formation, undoubtedly aggravate any predisposition to stone formation which may already exist.

Food alone can not materially promote stone formation by its quality, although where the tendency exists it may be intensified by the quality of the food. Thus, in India, Vandyke Carter found oxalate-of-lime nuclei among the calculi of the rice-eating natives. But it is not starch as food that causes stone, or the potato-eating Irishman would be prone to it, which is not the case; nor is it rice-starch, or the Chinaman would be as constant a stone-producer as the Indian—which, again, is not the case.

In Europe and America uric-acid stones are the rule; but, if a meat diet caused stones, the latter would be much more common in cities, where much meat is consumed, than in the surrounding country—which, again, has not been noted as a fact.

Abundance of milk as a diet has been supposed to avert tendencies to stone, and probably this is true, but alone it is an insignificant factor. Indigestion, again, has been accused of causing stone formation, but, if indigestion alone were a main cause, surely the disease ought to be rampant in New England, where hot bread, pie, and rapid eating, with accompanying bad teeth and dyspepsia, are the order of the day among the people; and yet stone is very rare in New England. A possible reason for the relative frequency of oxalate of lime in the calculi of India may perhaps be found in the well-known disturbances of the liver which are said to be common in that climate, the cause of oxaluria being often, in this country at least, associated, if not identical, with functional hepatic disturbance.

Constitution.—It is probably not doubtful that gout and rheumatism increase any existing tendency there may be to stone formation, because these diathetic conditions are accompanied by acidity of the urine as a rule, with a tendency to abundant excretion of uric acid, urates, and the like. A gouty individual, leading a sedentary life, drinking beer and champagne and eating a highly nitrogenized diet, especially if he does not exercise, having a little dyspepsia, and constantly kept anxious about his business, is exactly in a fit condition to form stone easily. Cases of kidney colic with the passage of small acid concretions are constantly furnished by this class of individuals.

Allowing, then, if the foregoing representations are accurate, that water, climate, soil, occupation, exposure, digestion, alcohol, and food are not responsible for the geographical distribution of stone, granting some weight to race and social condition and considerable influence to the rheumatic diathesis, what factor remains to be considered, for surely these alone are not entirely sufficient?

The only one which seems capable of filling up the gap is heredity.

As gout is hereditary, so are the tendencies to stone. I have at present under observation a family in which three generations, all living, have strong and constantly outcropping tendencies to the appearance of fine uric-acid gravel. The baby of four years and the grandfather of seventy manifest it about equally. Mr. William Cadge,* in discoursing recently to the Norwich Medico-Chirurgical Society about a woman with sacculated bladder and stone, mentioned that the patient's father had died after lithotrity, and that her brother, living in Buckinghamshire, was then said to be suffering from stone. The most celebrated recorded instance of inherited tendency to stone, so far as I am aware, is that reported by Mr. Clubbe,† of Lowestoft, where six children all had stone, the father and mother passed quantities of uric acid, the grandfather, grandmother, great uncle, six uncles, four aunts, and a cousin, all had had attacks of gravel or had been cut for stone.

It seems to me not very improbable that hereditary tendency lies at the bottom of the regional distribution, and largely accounts for the peculiar geographical localities of stone. Generation after generation, growing up in the same region of country and intermarrying, would naturally reproduce and intensify any such physical trait as a tendency to stone. I am aware that it has been claimed that strangers going to Norwich have developed stone, having shown no tendency to it in their own land; but it would take a large array of such facts to constitute anything more than a coincidence.

In former years of slow locomotion the few who emigrated married others with different tendencies, and so failed to spread the habit, or married others with like tendencies, and thus established new areas of stone formation.

Food, drink, and surroundings may have intensified or modified these natural tendencies more or less, but that the essence of the geographical distribution of stone (primary, acid stone) lies in intensified and reduplicated hereditary predisposition seems to me at least plausible in lack of a better general explanation.

With modern improvements in rapid transit and facility and cheapness of locomotion, it seems at least possible that the centers of stone formation may be somewhat broken up, and, by more general and mixed marriages, the disease become more extended in geographical area, but less active.

1 PARK AVENUE.

THE INCOMPATIBILITY OF IODIDE OF POTASSIUM WITH SULPHATE OF QUININE.—The Paris correspondent of the "British Medical Journal" says: At a recent meeting of the Société de Biologie, M. Rabuteau made a communication concerning the incompatibility of iodide of potassium with sulphate of quinine. He frequently observed that when these two substances are administered together, or one a short time after the other, even in small doses, such as one gramme of iodide of potassium and half a gramme of sulphate of quinine, anorexia, nausea, and even vomiting frequently ensue, accompanied by colic. The pulse becomes feeble, accompanied by paleness, and a feeling of worry and fatigue.

CELLULITIS OF THE ORBIT.*

By THOMAS R. POOLEY, M. D.

THE gravity and importance of inflammation of the cellular tissue mainly depend upon the situation in which it occurs. This is especially true of the loose connective tissue which is so plentiful in the orbit, because of the disastrous results which may ensue to the integrity of the eye by the pressure which the swollen and hardened cellular tissue exerts upon the optic nerve and the blood-vessels which supply the eye. At the last meeting of the society, Dr. Williams, of Boston, made some very interesting and practical remarks upon "Orbital Cellulitis as a Sequence of Facial Erysipelas." While reference will be made to an unusual and interesting case of this kind, which I am allowed to use through the kindness of Dr. Knapp, my remarks will, in general, have to do with a less dangerous form. The literature, especially of late years, on this subject is very voluminous, and it is no part of my plan in presenting this subject here to attempt to refer to all the papers I have read. I shall confine myself to a brief consideration of the more important facts in connection with the two cases I desire to report. Both of these cases belong to the so-called idiopathic forms of cellulitis, and terminated favorably.

CASE I.—On the 27th of March, 1883, I was asked to see the ten-year-old daughter of a colleague. I found that the child had been obliged to come home from school the day before because she felt too ill to attend to her studies. There was, however, very little pain, but a general feeling of malaise. The next morning the lids began to swell, and there was a feeling of pain and tension in the left eye. By the time I saw her there were very considerable tense swelling of the eyelid and some chemosis, but no purulent or other discharge, except lachrymation. The lids were very hot, the tongue was somewhat coated, the pulse was rather frequent, the movements of the eye were not restricted, nor was there any noticeable degree of exophthalmus. In the belief that the case might develop into diphtheria of the conjunctiva, I ordered the constant use of ice compresses. In the course of the next day or two the character of the disease remained much the same, but no diphtheritic membrane formed on the lids. On the contrary, the symptoms now pointed very clearly to an orbital process. The eyeball began to show moderate protrusion, and became restricted in its movements in all directions. I told the father that there was evidently cellulitis of the anterior portion of the orbital cellular tissue, and advised the use of hot applications, and, should the severity of the symptoms increase, the possible necessity for an incision. An examination of the fundus showed no symptoms of pressure on the central vessels of the retina or the nerve.

I asked the father to call Dr. Agnew in consultation, which was done on the following day. He agreed with me as to the character of the affection, and suggested, in addition to my treatment, the use of calcium sulphide, one-tenth grain every two or three hours. At the suggestion of the child's father, we also gave a full dose of calomel. In a day there was marked improvement, less protrusion, and freer movements of the eye, with diminution in the swelling of the lids. I now interrupted the hot applications for some hours, and applied a pressure-bandage. Under this plan of treatment rapid recovery ensued,

the child had quite recovered in a week, and in ten days from the beginning of the attack went back to school. In regard to the cause of the disease, most carefully sought for, we remained in ignorance.

CASE II.—W. D., twenty-four years of age, had contracted syphilis, and had at the time I saw him secondary manifestations of a late character, also stricture of the urethra, for both of which conditions he was under the treatment of his family physician, Dr. C. F. Roberts. The evening of the day before I was called to see him, in consultation with his physician, after a long drive in the cold he had a severe chill, followed by pain in the head and in the left orbit, which became toward night excruciating in character. This was very soon followed by swelling of the lids and protrusion of the globe. I saw him the following night, November 19th. He looked extremely pale and haggard, and was evidently suffering great pain. I found both eyelids swollen, dark red, hard, shining, the conjunctiva chemotic to such an extent that it protruded beyond the eyelids; the eyeball was moderately protruded and almost immovable; any effort to make movements was accompanied by great pain. The pupil was moderately dilated, the cornea was sensitive, the ophthalmoscope showed a normal fundus, and his sight seemed unimpaired. No fluctuation could be found, but the outer border of the orbit seemed to be somewhat sensitive to pressure. His pulse was about 110; the temperature not taken at this visit. I made the diagnosis of acute cellulitis of the orbit, and directed that hot compresses be applied to the eye throughout the night. He was also given a hypodermic injection of morphia to still the pain, which was intense. Early the next morning I met his physician, prepared to make an incision into the orbit to liberate pus, which I fully expected would be formed by that time, but we found the patient so much improved that we determined to wait. The pain was less, and so were the swelling of the lids and the exophthalmus, the eyeball moved more freely, the pulse was less frequent, and his temperature in the mouth was normal. Moreover, the ophthalmoscope showed no evidence of any embarrassment of the circulation in the eye nor change in the optic disc.

Under these circumstances we staid our hands, and directed a continuance of the hot applications. In the evening the improvement was still more decided, and the compresses were continued through the night. November 22d, the swelling of the lids was still more abated, the exophthalmus was almost gone, movements of the eye were apparently restored, except a slight impairment in both lateral directions. It was now directed that he should have the hot compresses applied for an hour three times a day, and a pressure bandage, as firmly as he could bear, in the interim. November 23d, the swelling of the lids, chemosis, and exophthalmus were gone. Movements of the eye seemed to be normal, but, in looking obliquely upward to the right, he saw double. From this time on he made a perfect recovery, although the diplopia persisted for some days. It may be added that there was no evidence of gonorrhoeal rheumatism in any of the joints, nor of periostitis.

The speedy and complete resolution, without the inflammatory process going on to the formation of pus, in both of these cases was very gratifying.

In the first case the disease was evidently not of severe character, and it seems probable only affected the anterior portion of the orbital tissue; but in the other the violent onset of the disease suggested that the area of tissue affected was much larger, and extended to the depth of the orbit.

The brief description of these two cases suffices to bring out the salient symptoms of the disease; but let us enumer-

* Read at the annual meeting of the Medical Society of the State of New York, February 5, 1884.

ate them more in detail. As prodromes, we have chill, fever, cephalalgia; sometimes vomiting and epistaxis; occasionally delirium and convulsions; protrusion of the eye, which generally sets in suddenly (the direction of the deviation is, as a rule, straightforward, or forward and outward); impairment of the normal movements of the eye, very variable in degree, according to the severity of the process. This symptom may affect only the movements in certain directions, or all the muscles may be involved to such an extent that the eyeball remains immovable. As a consequence of this, diplopia may occur at any stage of the affection, until the poise of the muscular force is restored to the normal. Swelling of the lids is the most constant and earliest symptom. In most instances the upper lid is the more swollen of the two. If, however, the orbital inflammation has been excited by disease in the antrum of Highmore or dental caries, the maximum swelling may be in the lower lid. The characteristic swelling of the lid is oedematous or a high grade of hyperemia, rarely caused by pus-infiltration. Chemosis, or swelling of the ocular conjunctiva, is also among the earlier and constant symptoms; in many cases it is very great, as it was in our second case, being sufficient to force the conjunctiva between the lids.

Mydriasis is often present, but in some cases the opposite condition of the pupil, myosis, is seen. In some cases, too, there may be anaesthesia and sloughing of the cornea.

But by far the most interesting and important feature of the disease is the effect it may produce upon vision; this may amount to amblyopia or amaurosis. Leaving out of the question some of the modes by which sight may be lost—such as sloughing of the cornea, an extension of the purulent process to the eye, producing panophthalmitis, and so on—I simply desire to make some few remarks upon the affection of sight caused by pressure on the optic nerve and blood-vessels which supply the eye in the orbit, especially as by Dr. Knapp's courtesy I can present a very remarkable and unusual case, and show the ophthalmoscopic drawings. It is generally assumed that the loss of vision is due to inflammation of the optic nerve, with subsequent atrophy, or to atrophy without inflammation, caused by pressure on the intra-orbital portion of the nerve. There is, however, a lack of observation based upon the examination during the first stage of the affection, which makes his case of great interest and value. It would seem that, while opacity of the retina, such as occurs in embolism of the central retinal artery, has been observed, the reason which has been assigned for the consecutive blindness in most cases of orbital phlegmon is atrophy of the nerve as a sequence of neuritis. This view seems not to be borne out by direct observation. From Dr. Knapp's observation it would seem more rational to assume that not only the atrophy of the nerve, which is seen as the final ophthalmoscopic picture, but even phthisis of the globe and sloughing of the cornea may be due to thrombosis of veins and compression of the retinal artery. On account of the importance of this view, I may be allowed to give a brief abstract of Dr. Knapp's case* before showing the drawings:

A patient, forty years old, who had syphilis, had an attack of erysipelas which began in the nose and extended to the pharynx, cheeks, and orbits; thence reached the forehead, both ears, and both sides of the neck. Five days after, when the general symptoms abated and the pulse and temperature were normal, the lids remaining swollen, chemosis and exophthalmus appeared. Two days later the sight of the right, and three days later that of the left eye was impaired, and the next day he was quite blind. It was then that Dr. Knapp first saw the patient. Both eyes showed the usual symptoms of cellulitis, which have already been enumerated. Incisions had been made in the orbits. The pupils were wide and immovable. The right cornea had a superficial ulcer, but the media admitted a clear view of the fundus. The drawings, executed in chromo-lithography,* which I shall pass round, show the appearances which are thus described and interpreted by Dr. Knapp. The retina was milky white, pervaded by numerous dark, almost black, tortuous, surcharged blood-vessels, which, tapering, converged to a common center, and had upon and between them many irregular, dark hemorrhages. The character of all the vessels was the same; they appeared as large veins. The picture resembled that seen after resection of the optic nerve, and Dr. Knapp gave his opinion that the ocular affection was thrombosis of the retinal veins, and complete obstruction of the central retinal artery by compression from the swollen and indurated cellular tissue of the orbit. Two days later, the milky appearance of the retina was less, vessels and the hemorrhages were the same; the whole disc was non-recognizable. Two days later, the disc was well defined, homogeneous, pervaded by two tortuous, thin vessels—the superior and inferior branches of the central arteries. In the next three succeeding ophthalmoscopic examinations the disc-margin became better defined; some portions of both the arteries and veins were interrupted by white lines; the veins were less dark; the discs quite white. Three weeks and three days after the first examination, the condition of the left eye was: disc white; arteries and veins clearly seen; arteries in some places bordered by white seams [opacity of vascular walls by defective nutrition, and, like the veins, in some places interrupted by snow-white lines [white thrombi]]. The veins in some places appear nodular, but there is no movement of the contents of the vessels, either spontaneously or by pressure on the eye. Hemorrhages still numerous.

The final examination, nearly two months after the accident: In region of yellow spot, a network of anastomosing white lines; retinal tissue semi-transparent, with white patches, especially in region of yellow spot. The two inferior vessels (inverted image), one artery and one vein, red. The patient remained blind in both eyes.

In this case it seems quite clear that there was, as pointed out by the author, compression of the central artery and subsequent thrombosis of the veins, both of which were observed by Dr. Knapp with the ophthalmoscope, and from beginning to end no neuro-retinitis, but, as beautifully shown in his drawings, the successive stages of thrombosis.

Several years ago I made an observation of a somewhat similar character, although far from being so complete. In the case of a man who was shot in the temple, immediately following the injury there was enormous protrusion of the eye, with complete loss of sight. I saw him a few minutes after, and made an ophthalmoscopic examination.

* Will be published by Dr. Knapp, in connection with a detailed description of the case, in Vol. XII, No. 1, of the "Archives of Ophthalmology."

* Reported at the meeting of the Am. Ophth. Society, July, 1883.

The whole retina was milky white, and I could nowhere detect any arteries, but the veins were full of dark blood and tortuous. There were no hemorrhages.

The next morning the cornea was already so hazy that I could no longer make an ophthalmoscopic examination; it soon sloughed. Panophthalmitis and phthisis bulbi resulted. This eye was probably lost by the extravasated blood, which filled the orbit, acting in the same way as the hardened cellular tissue does in cellulitis, compressing the artery and causing thrombosis of the veins.

The diagnosis of acute cellulitis of the orbit from other affections is not difficult, and yet there seems to be a good deal of confusion existing in the text-books on this point. The important affections for which it may be mistaken are:

1. *Suppurative Irido-choroiditis*.—In this affection the eye is first affected, and then protrusion ensues only when the inflammation has reached its height. The symptoms are referable to the eye rather than to its surroundings, such as intense pain in the globe, clouding of the media, and change in the iris, so that it is hardly possible to make an error in the diagnosis. It should be borne in mind, however, that this condition may ensue in the course of the orbital affection after perforation of the cornea has taken place.

2. *Inflammation of the Lachrymal Gland* may bear some resemblance to orbital phlegmon, but, if the former condition be present, the eye will be displaced downward and inward, and a tumor will be felt in the upper outer part of the orbit, which will be painful to the touch.

3. *Inflammation of Tenon's capsule* may bear a striking resemblance to orbital phlegmon, as the symptoms under which it begins are much the same—protrusion, and obstruction in the movements, of the globe, chemosis, and diminution of vision. The important point to remember in the differential diagnosis is that swelling of the lids occurs later, or not at all, in the course of this disease. It is far more difficult, when both of these affections coexist, to distinguish which was the primary affection. In inflammation of Tenon's capsule the formation of the abscess is in the cellular tissue, between the fibrous capsule and the globe. The loss of sight in these cases comes not from compression of the nerve or blood-vessels in the orbit, but mostly from the pressure directly exerted upon the eyeball itself. The blindness also comes, without exophthalmus, by gangrenous perforation of the sclera either in its anterior or posterior part. The pus from an abscess of Tenon's capsule, moreover, is not, like that which comes from the depth of the orbit, mixed with flakes of cellular tissue, but consists of a clearer fluid, such as would emanate from a preformed abscess, sac, or cavity.

4. It may be difficult to distinguish primary inflammation of the cellular tissue from *periostitis* and *caries of the orbit*, but in the latter affection the swelling will be more marked in the upper or lower margin of the orbit, which will be at the same time exquisitely sensitive to pressure, whereas this localized sensitiveness is not characteristic of orbital cellular inflammation. If the periostitis is in the posterior part of the orbit, the differential diagnosis may be difficult or impossible. If the pain is more severe when the globe is pressed against the walls of the orbit than when

pressure is exerted from before directly backward against the cushion of orbital cellular tissue which lies behind the eyeball, the inference is in favor of a periostitis.

Treatment.—The application of leeches, the use of cathartics, mercury, and so forth, as formerly practiced, are worse than useless, and, so far from having a favorable effect, can only aggravate the disease by weakening the patient.

The application of cold, too, even in the formative stage of the disease, is not likely to abort it, but its continued use may produce gangrene of the tissue. Warm applications constantly applied are of the greatest value, and, in both of the cases I have reported, were followed by immediate amelioration of all unfavorable symptoms. So soon as the swelling of the lids and the exophthalmus begin to subside, the cure will be hastened by the application of a pressure-bandage firmly applied. The necessity for surgical interference must be judged of by the gravity of the case. An incision, or, as some recommend, a simple puncture, or several punctures, may be made before fluctuation can be felt. There can be no doubt of the propriety of an early incision if the exophthalmus is of high grade, the eyeball immovable, the lids very much swollen, and sight threatened; but, in the majority of cases, it will be safe to wait until fluctuation can be felt, in the hope that resolution will ensue and the necessity for surgical interference be avoided. In the event of an incision being determined upon, it should be made, unless fluctuation be present in some place, in the most dependent part of the orbit. It seems to me to be of very little moment whether it be made under antiseptic precautions or not; nor do I think it important that a drainage-tube be used unless caries of the orbit be present; it will be better to let the wound close as soon as the pus is evacuated or the tension relieved; and, if there be caries of the walls of the orbit, the wound will remain open of itself. All that is necessary is to keep the tract of the wound carefully cleansed with an antiseptic solution. The incision into the orbit may be made through the conjunctival sac or through the lid. If care be taken to make the incision parallel with the course of the fibers of the orbicularis, it is just as well to make it through the integument, which admits of more ready access to the wound, for the purpose of drainage and cleansing.

THE PREVENTION OF PUERPERAL INFECTION.

By HENRY J. GARRIGUES, A. M., M. D.,

VISITING OBSTETRIC SURGEON TO THE NEW YORK MATERNITY HOSPITAL.

THE "Medical Record," in an editorial of January 5th, commenting on my paper on "The Prevention of Puerperal Infection," read before the Medical Society of the County of New York,* says: "To the unbiased mind it is clear as day that Dr. Garrigue's [read Garrigues's] remarkable success is due to non-interference with the traumatic utero-vaginal tract after completion of labor, rather than to the aseptic napkin."

* "Medical Record," December 29, 1883; also an abstract in this journal of the same date.

Dr. Simon Baruch says, in No. 7 of the same journal, patching one part of my paper together with another: I "quote Dr. Garrigues's experience as evidence of the inutility of these injections" (i. e., vaginal injections after normal labor). A little farther on he says: "The experience of Dr. Garrigues may also be cited in support of the view that injections after labor are dangerous, producing or keeping up fever processes. Despite his most active antiseptic prophylaxis, this careful observer was forced to admit that a large and very serious percentage of puerperal fever processes continued, and that the mortality rate was still unsatisfactory. But, so soon as he adopted the course of abstaining from the only injurious element of his prophylactic method, 'the vaginal injection twice daily,' a complete change occurred." Finally, he says that "few judicial and discriminating obstetricians will fail to accept the marked success more as an evidence of the [harmfulness of the injections in the first series of cases than as a demonstration of the value of the pad [i. e., my dressing impregnated with bichloride of mercury] in the second series."

Although these writers have a perfect right to think they understand much better than I a series of observations which I have taken the greatest possible interest in making during several years, and in spite of my doubtful judgment, discrimination, and freedom from bias, I hope it will be conceded on all sides that as to *facts* relating to my own practice nobody can be better informed than myself. Now, I am sorry I have to say that all these conclusions, from my experience in regard to the inutility and danger of prophylactic vaginal injections after normal labor and of the value of non-interference with the utero-vaginal tract, are unwarranted, since *neither during the first nor during the second of the periods which form the basis of my paper did I use vaginal injections after normal labor in Maternity Hospital*. My object in writing the said paper being only to show the value of the bichloride of mercury and of my way of using it, I did not enter on the discussion of the injections, although I stated plainly that I regarded it as one of the advantages of the treatment described that, "by the effective antiseptic treatment at the entrance, preventive injections become superfluous, and thus one great source of infection is avoided."

Having been well pleased for years with the vaginal injections of one- to two-per-cent. carbolic-acid solutions morning and evening as routine treatment, I used them likewise in Maternity Hospital when I was appointed visiting obstetric surgeon there in 1881. During my first service of six months there reigned a moderate morbidity and mortality, but still, not satisfied with the general condition of the patients, when I went on duty again, on October 1, 1882, I wanted to try if perhaps the vaginal injections, administered by nurses who often came directly from the wards of Charity Hospital, did more harm than good. I therefore abolished them, and they were not used during the following six months. At that time the preventive measures consisted only in dusting the outside of the external parts with a mixture of salicylic acid, one part, and starch, four parts, and inserting a pad of oakum between the thighs. *In spite of this system of non-interference, the morbidity and mortality increased very much.*

The hue and cry recently raised against vaginal injections exaggerates, in my opinion, very much the dangers of this mode of treatment. For ten or fifteen years they have been used by the most advanced obstetricians. They came in as part of the antiseptic treatment, by which the results obtained in lying-in institutions have been entirely changed all over the world. Since its introduction, so-called epidemics as they used to occur, in which sometimes for months one out of three puerperæ died, have become impossible; and, even without taking into consideration these exceptional periods, the mortality from puerperal fever was in good institutions brought down from five to one or two per cent.

It ought to be distinctly understood that *antiseptic vaginal injections are by far preferable to the abstention from all antiseptic treatment*. But it is in the nature of things that we constantly try to do better, and, if we can find an antiseptic treatment that allows of safely dispensing with the vaginal injections, it is to be preferred. Vaginal injections present, namely, several drawbacks. They necessitate the use of a particular apparatus, which increases the expense of the lying-in period, and thus become more difficult to obtain for the poorer patients. They necessitate, furthermore, the frequent contact of the fingers of the nurse and of the nozzle of the syringe with the genital tract of the puerperal woman, and the admission of the surrounding air into this canal, by all of which she is exposed to inoculation of septic material. Even the simple mechanical disturbance of the wounds constantly found in the genitals after delivery may retard their healing. Finally, some degree of nicety in manipulation, and, consequently, a comparatively developed intellect, are required of the person intrusted with the administration of vaginal injections.

All these objections apply only to injections after delivery. Those before delivery may be and ought to be given by the accoucheur himself, and, if no syringe is found in the house, he may use his own. I always carry one for that purpose in my satchel. *A thorough cleansing and disinfection of the vagina before delivery forms a link of absolute necessity in antiseptic midwifery*, for that alone prevents the introduction of material into the remoter and much-better-protected uterine cavity from the vagina and vulva, which form a kind of open avenue accessible to the outer air, bathed with urine and coming in contact with different foreign bodies.

It has been said that the disinfecting fluid does not come in contact with the whole vagina on account of its folds. I think this is a mistake. When we give a vaginal injection it is easy to see that we inject a considerable amount of fluid before any of it returns. The first effect of the injected fluid is to distend the vagina and smooth out its folds, and thereby the fluid is really brought into contact with the whole surface of the vaginal wall.

Another objection that is made is that the carbolic-acid solution in the strength commonly used does not kill the bacteria; but much may be said against this argument. Thus, we know there are bacteria and bacteria, and only some particularly tough ones resist a five-per-cent. solution. Perhaps the two-per-cent. solution is all that is needed for

those which are found in the vagina. Then, there is no doubt that the number of bacteria has some influence. The organism may be able to overcome a certain unknown number of them, and not a larger one, and, consequently, the mere mechanical removal of bacteria, if they be the offenders, may be useful. But, since now we give up carbolic acid and substitute a real germicide, bichloride of mercury, this objection can at best be applicable to the antiseptic treatment of the past. In all that refers to antiseptic surgery and obstetrics, we must remember that the correctness of the theory has by no means been proved. We can only go by the wonderful results, and are only warranted in the conclusion that by our treatment we exclude some kind of dangerous element the nature of which is not yet known. But, whatever it may be, the practical man will give his patients the advantage of a treatment which in practice has proved greatly to increase their chances of a speedy recovery.

Besides vaginal injections, I have used and continue using prophylactic *intra-uterine* injections in every case in which it has been necessary to introduce fingers, the whole hand, or instruments into the uterine cavity. The theoretical reason for this is that, even when the vagina, the hand, and the instruments are disinfected, it is impossible to avoid introducing air into the utero-vaginal canal, and, as this air may carry poisonous elements, the parts must be disinfected. Formerly I used for this purpose a five-per-cent. solution of carbolic acid; now I employ the 1-to-2,000 bichloride-of-mercury solution. I likewise use this prophylactic *intra-uterine* injection when the *fœtus* has been dead for some time.

Although it is outside of the scope of these remarks, I will only briefly add that, as a curative remedy, I have seen excellent results of *intra-uterine* injections, and I use vaginal injections three times a day or oftener if the lochial discharge has any *fœtor*; but since I have been using my new dressing this has become quite rare.

I showed in the beginning that my recent success in Maternity Hospital had nothing to do with the use or non-use of vaginal injections. I attribute it myself chiefly to the use of the bichloride of mercury and to the careful application of the bandage, and I do not think I can be much mistaken in this respect, since these are the two chief points in the new treatment. The bichloride of mercury has been experimentally proved to be a true germicide even in a much more dilute solution than the one we use.

I have never been able to trace the infection of the patients to doctors or nurses, but everything pointed to a poison in the air in the wards, which was somewhat subdued, but not exterminated, by sulphurous acid. I conclude this from the fact that when a new ward was used, in which there had not been any puerperal patients for years, all went well there for a long time, and that even in the other wards, as often as they had been fumigated, the temperatures of the patients were normal for about a week, when fever reappeared.

The form of puerperal fever we had especially to deal with was diphtheritic inflammation, and the places in the genital tract in which it almost invariably began—namely,

on the labia or at the vaginal orifice—pointed decidedly toward an infection coming from without. The indication was, therefore, to find a better antiseptic than carbolic or salicylic acid, and to apply it in such a way as to exclude the air from the genital canal, or at least only to admit it through a disinfecting filter. I decided to try bichloride of mercury, and applied it in the way described in the paper read before the county society. This method has proved as safe and sure as it is simple. It has now been used in one hundred and seventy-five confinements in Maternity Hospital, and in the same wards where we used to have constant trouble everything goes smoothly. Every trace of infection has disappeared, and there has been remarkably little disease of any kind. In some cases of inflammation of the womb and its surroundings we have even observed the interesting phenomenon of an inflammation running its course without any rise in temperature.

I use the same treatment in private practice, with rich and poor, and it gives the same satisfaction. Ladies who have had children before find the dressing very pleasant, and delight in the absence of odor, not only of carbolic acid, but of the lochial discharge.

Having been asked by several practitioners how I arrange the details in private practice, I will give the particulars here. I carry powders of 15 grains of corrosive sublimate in my satchel, in order to be sure to have them on hand. After confinement I prescribe powders with $7\frac{1}{2}$ grains. I dissolve the 15 grains in a quart of hot water, stirring with a wooden spoon. This forms a solution of about 1 to 1,000, which, according to circumstances, is mixed with an equal amount of hot or cold water, thus forming a solution of 1 to 2,000, which is the strength used for all purposes. I dispense with the disinfection of the abdomen, thighs, and buttocks, deemed necessary in the hospital, but inject invariably a quart into the vagina, placing the patient on a bed-pan. If the latter utensil were not obtainable, it might easily be replaced by some contrivance which will present itself to the mind of the practitioner. In tedious cases I repeat this injection according to circumstances, at least once in three hours, in which case it serves both as a disinfectant for the vagina and as a stimulant for the uterus. When the presenting part appears, I apply to the vulva a piece of lint dipped in the solution, except, of course, in precipitate labor. After the birth of the child and the removal of the after-birth I wash the patient with the solution; apply a binder; cover the genitals and anus with a piece of lint, wrung out of the solution, eight inches long, and folded so as to form four layers three inches wide, which is exactly the width of the space between the genito-femoral sulci in most women; place outside of the lint a piece of oiled-silk which is an inch longer and broader; put a large pad of carbolized cotton on top of the oiled-silk, and fasten the whole tightly to the binder. For the binder and this piece between the legs I prefer Canton flannel, but any clean muslin or linen will do. The principle in this bandage is to have an absorbent wrung out of the solution of bichloride of mercury in immediate contact with the genitals, a water-proof substance outside, in order to prevent the bichloride from being absorbed by the

external parts of the dressing, and a dry and soft absorbent outside the waterproof material, in order to take up the discharge which exceptionally escapes from the inner compress, to form a first filter for the air, and to keep the inner compress in contact with the skin. Where strict economy is necessary, the lint may be replaced by muslin or cotton batting, the oiled-silk by gutta-percha tissue, and the carbolized cotton by common cotton or any clean rags. If the perineum has been torn, it is stitched up before applying the bandage, but all other wounds are left entirely to themselves under the protection of the dressing. Three times a day the outside of the genitals and surrounding parts are washed with the solution, and the dressing is renewed. For this purpose the person in charge of the patient dissolves one of the $7\frac{1}{2}$ -grain powders in a quart of warm water. No trained nurse is required, the procedure being so simple that the husband or any female friend can perform it.

The simplicity of this treatment is apparent; its safety for patients, nurses, and doctors is demonstrated by the total absence of any kind of untoward accidents during the five months it has been in use; and its efficacy is proved by the radical change in the condition of the patients in a hospital that abounds in unfavorable hygienic features, and in which disease used to be permanent and death frequent.

137 WEST TWENTY-SECOND STREET.

A CASE OF RUPTURE OF THE UTERUS.

By SAMUEL D. GILBERT, M. D.,
NEW HAVEN, CONN.

At three o'clock A. M., December 2, 1883, I was called to attend Mrs. C., a native of Ireland, aged thirty-four, in her fifth confinement. I attended her in her fourth confinement November 6, 1881, which, like all the previous ones, was natural in every respect. She was a strong, healthy woman, and had four children living.

On examination *per vaginam*, I found the os uteri of about the size of a dime, not rigid. Diagnosed a breech presentation, which proved to be correct. The vagina and genital parts were cool and moist.

On examination of the abdomen externally, I found the head lying toward the left side, and I was struck with the fact that it seemed just under the skin, so thin were the uterine walls. Remained an hour, when, as the pains were slight and infrequent and the patient was in good condition, I left. Saw her again at 8 A. M., but, as there was no change, left directions that I was immediately to be summoned in case "good labor pains" began, and went about my day's work. Was called at 10.30 P. M. the same day, and reached the house, about three miles distant, at 11.30. Found the os uteri nearly fully dilated, but the pains infrequent. As the woman was tired and nervous, I thought best to deliver. I ruptured the membranes and waited fifteen minutes, when, as there was no decided uterine action, I proceeded to deliver, having given chloroform, not to the extent of full anesthesia, but a quantity sufficient to prevent the patient suffering much pain. I had great difficulty in the delivery, as the child was large and the parts were tense. It was fully half an hour before the lower extremities and the body and arms were born. When I had brought down the last arm the os contracted around the neck of the child with the grasp of a vise. After fifteen minutes the head was extracted, and, though I was as gentle as I could be, considering the force necessarily used, when the head emerged from the os there was a distinct and sharp tearing sound, and the patient instantly collapsed.

The child, a female, was dead, and exhibited on the left parietal bone a depression, circular, and one inch and a half in diameter, with sharp edges. This was evidently a malformation, and not in any way occasioned by any deformity of the pelvic bones, which I am quite sure did not exist. I immediately gave my attention to the woman. Placing my left hand on the fundus, which contracted promptly, I found, on following up the funis with my right hand, that it did not lead into the uterus, but through a rent which extended through the cervix and perhaps into the body of the uterus slightly. (I had no time to make a very careful examination of the rent, as the woman was in collapse and apparently about to die.) I promptly passed my hand through the rent, following the funis into the cavity of the abdomen, and fortunately found the placenta without much difficulty and removed it. The patient's whole condition was bad, the pulse exceedingly weak and thready; a large amount of blood was lost.

I at once resorted to stimulants and ergot, surrounded her with hot flat-irons, and, after half an hour, there was a fair reaction—much to my satisfaction. I then remained two hours, when, as reaction was well established, I went home. I visited the patient on the morning of the 3d, about 10 A. M., and found her much more comfortable than I anticipated. The pulse was of fair volume and strength; the temperature about 100° F.

The abdomen was very tympanitic and exceedingly tender on pressure. Urine had been passed. Ordered sulphate of morphine, gr. $\frac{1}{4}$, to be given every two hours, unless the patient slept or was entirely free from pain. (The morphine was administered in full doses for eleven days, or until convalescence was well established.) Hot turpentine stupes were applied to the abdomen. When I made my first visit, December 4th, I found the lochia were quite offensive, and ordered the injection well up into the vagina of a gallon of warm water with 2½-per-cent. solution of carbolic acid. This was repeated twice daily, as long as there was any discharge, during a period of three weeks. From this time the patient did well, though, of course, the condition was a grave one. There were great tympanites and tenderness for several days, and an offensive discharge containing pus in considerable quantities, but all the bad symptoms gradually diminished.

The temperature never went above 104°, and only on one occasion over 103°. In a fortnight convalescence was well established, and in a month the woman was up and about the house doing her housework in a great measure. This was contrary to my wish, but she felt the necessity, as she was poor. She is at the present time, February 1st, quite well.

This differs from the majority of cases of rupture of the uterus reported, in the time and manner of its occurrence, and also in the result.

I attribute the recovery of the patient, firstly, to her good constitution; secondly, to the full doses of morphine used continuously; and, lastly, to the thorough washing of the genital tract with an antiseptic solution. I did think at one time of injecting the solution through a glass drainage-tube directly into the cavity of the abdomen, but, as I could not well do it myself twice daily, and the patient had to depend on a poor nurse, I had her use the vaginal injection. The result shows that it was sufficient.

"DEATH FROM MISADVENTURE," according to the "Lancet," was the verdict at a recent inquest, in London, on the body of a man whose death was shown by the medical evidence to have been caused by chloral, which he had been accustomed to take to induce sleep. There seemed to have been no motive for suicide, and it was presumed that he accidentally took an overdose of the drug.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

NEW YORK SATURDAY, MARCH 1, 1884.

THE SUPPLY OF ANATOMICAL MATERIAL.

WHILE it is undoubtedly true that no intelligent and well-informed person can question the duty of the law-making power in the several States to provide for the reasonable needs of the medical colleges in the matter of material for dissection and demonstration—while, in fact, the simple proposition has come to be recognized by such persons that the State can not justly hold practitioners of medicine as bound to possess an amount of anatomical knowledge sufficient to enable them to practice their profession with the best attainable degree of safety to the community, in so far as that sort of knowledge forms an element of safety in the practice of medicine, unless at the same time it provides the means of acquiring it—it is equally true that intelligent and well-informed people are not the only ones whose approval has to be secured before a legislative enactment that seems to run counter to the instincts of humanity can be procured.

It is on this account, doubtless, that several of the States are still backward in adopting the measures necessary to provide adequate means for the practical study of anatomy. In order to overcome the natural reluctance felt by legislators to passing laws they know to be abhorrent to a considerable proportion of their constituents, they must be convinced of the pressing need of such laws, and that the necessity is one that affects not only the medical profession, but, however indirectly it may be, the whole people. Not only do we feel that this is the one line of argument which alone is of any force, but we doubt exceedingly if the cause is not weakened by an appeal to arguments of any other sort.

Certainly this must be true of those attempts at persuasion, smacking of coercion, that are too often brought into play by medical writers, partly, we must suppose, under the actual conviction that they will have an effect in furthering the legislation sought for, but also (and it is this aspect which is apt to strike the general public) in palliation of the detestable crime of violation of the sepulchre. At best, the plea amounts to no more than this: Give us what we want, and we will no longer steal it; feed us, and we will refrain from playing the jackal! Of course, the medical profession takes no such ground as this; it entertains no such feeling; it realizes the criminality of grave-robbing, and properly detests the practice. Unfortunately, however, the great majority of the community of the country have no means of knowing the sentiments held in regard to such matters by the profession as a whole, and may be pardoned for judging of them by what is set forth by the self-constituted spokesmen to whom we allude.

It is indisputable that proper anatomy laws will do away

with the resurrectionist's wretched business, but that is not the ground on which we can reasonably, or even decently, ask for their enactment; and the community should understand that it is not the ground on which we do ask for it. Common morality forbids our taking any such position, but, quite apart from that consideration, the medical profession is too well informed to suppose for a moment that it can coerce the State by any course of the sort.

NEWSPAPER MEDICINE.

How it is that the details of marvelous surgical exploits so often find their way into the columns of the secular press is one of the standing puzzles of the century. It is well known that the fame thus easily achieved is disdained by the surgeons concerned, who, indeed, to say nothing of that consideration, would scorn to violate the code of ethics of the American Medical Association even where renown was to be reached only *per aspera*. Taking this view of the matter, apparently, the profession has never held them to any close accountability for not preventing this thrusting of greatness upon them. We must take it for granted, too, that most general practitioners, however much they may have chafed in the beginning at the monopoly of this sort of glory enjoyed by the surgeons, have gradually come to regard it as inevitable and as one of the natural prerogatives of a surgical career. The matter may assume a different aspect, however, if the newspapers take up obstetrics, and there are some indications that they are looking wistfully upon that branch of our art.

A recent Sunday issue of the "New Haven Register" treats its readers to almost a column and a half descriptive of the details of a Cæsarean operation, and it is only a few months since a Philadelphia newspaper gave about as full an account of a Porro-Müller operation. In both instances the names of the operators, as well as those of their assistants and the consultants, are given most impartially, coupled with glowing tributes to their skill and learning. In the New Haven case, it seems that the Cæsarean operation was lately repeated, with a fatal result, on a negress who had survived a like operation done more than fifteen years ago, at which time, as it was quite necessary for the "Register" to inform its readers, she was "an unmarried girl in her sixteenth year." The recent operation, which proved fatal, is dismissed with a short paragraph, but the minutest steps in the successful procedure of fifteen years ago are set forth without stint. The operation is characterized as a "brilliant performance," and the operator is thus enologized: "A few years ago the position of professor of surgery at Yale was offered him, but he felt obliged to decline. Had he accepted, the college would have resumed its time-honored reputation for the foremost surgical instruction." These preliminary flourishes are followed by a complete account of the case, taken from one of our contemporaries.

We wonder if the good people of New Haven relish this sort of Sunday reading, and we wonder still more how the medical faculty of Yale College like the broad insinuation that, because a certain person once declined the professorship of

surgery in their institution, the instruction now given there in surgery is not what it might have been.

THE PENSION INDUSTRY.

HONORABLE as the profession of medicine unquestionably is, its members can not all be said to be immaculate. We believe we are perfectly justified, however, in maintaining that for morality, fidelity to duty, and the general attributes of good citizenship, medical men are excelled by members of few if any of the other callings that expose their followers to like temptations. This, we think, is admitted by the community. If this enviable reputation is to be kept up, we must look to it that offenses are rebuked whenever they crop out, instead of being condoned or even ignored. In conformity with this manifest duty, we would ask if it is not getting to be rather too common to read in the newspapers of frauds upon the Pension Bureau perpetrated with the connivance of medical men. How many of these stories are true, and how many of them are founded on error if not on malice, it is impossible to say. Let us hope that the great majority of them belong in the latter catalogue. But, whatever the probability may be as to this point, the public can scarcely be expected to go on indefinitely giving us the benefit of the doubt. In many instances the reports are undoubtedly founded on fact, and it must be remembered that it is in great part only those in which there is a suspicion of fraud having been committed in the physician's own interest that are likely to find their way into the newspapers. How many more there are in which physicians aid in cheating the Government out of sheer failure to comprehend the fact that a baseless claim is not to be furthered, however interesting or unfortunate or in other respects deserving the claimant may be, without doing a wrong to all of our fellow-citizens—how many more cases there are of this sort, we say, it would be useless to try to estimate.

To evade the payment of taxes, or in some like manner to profit by withholding what one should contribute to the general funds, is too apt to be held venial; and still more readily are conscientious scruples smothered when it is not for our own profit, but to aid some poor sufferer, that we go beyond what the facts warrant in enabling a person to get a pension. All this is manifestly wrong, whatever plausibility there may be about such considerations as that the Government has a surplus revenue which might better be given somewhat recklessly to those who have suffered in its defense than squandered in schemes of so-called improvement of rivers and harbors and the like. Such a question is for the Government alone to settle; the medical examiner has nothing at all to do with it. The only inquiries with which the latter should concern himself are as to whether the alleged disability is a real one, and whether it was incurred in the line of duty.

MINOR PARAGRAPHS.

PRESCRIBING APOTHECARIES IN CANADA.

THE particular form of encroachment on the legitimate practice of medicine known as counter-prescribing is an old griev-

ance in this country, and one that we are scarcely likely to see the last of very soon, no matter what laws may be passed, or to whatever retaliatory measures we may resort. It is somewhat reassuring to find, however, that we are not quite so much ridden over in this way as our Canadian neighbors are, judging from an article in a recent number of the "*Union médicale du Canada*." It seems that one Montreal apothecary does so thriving a business in tooth-drawing, prescribing for gonorrhœa, opening abscesses, and the like, that he finds it necessary to employ a collector to gather in his *honoraria*. And yet the Canadian Medical Practice Act is most stringent. It may be questioned if either legal enactments or retaliation will ever suffice to eradicate the practice in question; our hope lies rather in the direction of an improved sentiment among the pharmacists themselves, the better portion of whom can not fail to see the lowering tendency of counter-prescribing.

SICKNESS IN THE JURY-ROOM.

SOME weeks ago we recorded an incident that was said to have happened in Philadelphia, the point of which was that a judge was made angry by the fact of a physician having been introduced into the jury-room on account of the illness of a juror. According to the "*Boston Medical and Surgical Journal*," a like incident lately took place in Massachusetts, and, on the strength of it, the defeated party in the action appealed to the Supreme Court. A small quantity of brandy was administered to the sick juror, but there was nothing to show, either that the spirit had in the least incapacitated him from doing his duty as a juror, or that the physician had entered into conversation with any of the jurors in a way calculated to prejudice the administration of justice. The appellate court held, therefore, that a new trial need not necessarily be granted.

A JOURNAL OF ORTHOPEDICS.

WE have received the first number of a most promising Italian journal of orthopedics, the "*Archivio di Ortopedia*," edited by Dr. P. Panzeri and Dr. F. Margary, and published in Milan. The number contains the following original communications: On the Operative Treatment of Inveterate Congenital Varus, by Dr. Margary; Mechanical Jackets in the Treatment of Scoliosis, by Dr. Secchi; Two Rare Deformities of the Leg corrected by Osteotomy, by Dr. Panzeri; A Case of Subtrochanteric Osteotomy for the Correction of a Grave Deformity from Coxalgia, by Dr. Novaro; and A Clinico-statistical History of the Cases of Genu Valgum treated by Operation at the Bambino Gesù and the Fate-Bene-Fratelli Hospitals in Rome, by Dr. Ceccarelli. Besides, we find a great variety of abstracts and a review of Vogt's "*Modern Orthopedics*."

SAUCE FOR THE GANDER.

NOW that a bill has been introduced into the British Parliament prohibiting the importation of cattle from any other country than Canada, it is amusing to observe the readiness with which the Germans accuse the British of aiming at the protection of their trade interests rather than the health of their own cattle. In view of the exception in favor of Canada, it is interesting also to note that a lot of diseased cattle lately landed at Liverpool, from a vessel that arrived from Portland, Me., came from Canada.

THE LATE DR. AMBLER OF THE NAVY.—The remains of the late Passed Assistant Surgeon James M. Ambler were taken from New York to his home in Virginia last Saturday, with an escort representing the medical and other corps of the navy. At Baltimore the party was joined by representatives of the

Medico-Chirurgical Faculty of the State of Maryland, of the faculty of the University of Maryland, and of the Clinical Society of Baltimore. The funeral train was received along the route with demonstrations becoming the occasion of the last rites paid to an officer who lost his life under circumstances calling for peculiar tenderness on the part of his countrymen. Medical Director J. M. Brown, Medical Director Albert L. Gihon, Surgeon W. K. Van Reyser, Surgeon C. M. H. White, Chief Engineer Melville, and Lieutenant Danephower were the pall-bearers.

NEWS ITEMS.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 26, 1884:

DISEASES.	Week ending Feb. 19.		Week ending Feb. 26.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	0	0	0
Typhoid Fever	21	6	11	5
Scarlet Fever	75	14	64	11
Cerebro-spinal meningitis	6	5	5	5
Measles	70	11	39	3
Diphtheria	47	20	44	23

THE UNIVERSITY OF VIENNA.—Dr. Widerhofer has been nominated ordinary professor of paediatrics, having been recommended, it is said, by Banberger, Nothnagel, and Braun von Fernwald.

THE PARIS FACULTY OF MEDICINE.—M. Tarnier, heretofore an agrégé, succeeds the late Professor Depaul as professor of obstetrics and diseases of women and children.

THE INTERNATIONAL OTOLOGICAL CONGRESS will be held at Basle, September 1, 2, 3, and 4, 1884. The titles of communications intended to be made to the congress should be made known to Dr. Burchhardt-Mérion, of Basle, before the 15th of May.

THE MEDICAL SOCIETY OF THE COUNTY OF HUDSON, N. J., will hold its next meeting on Tuesday, March 4th, at 4 p. m., at Taylor's Hotel, Jersey City. Dr. Charles F. Stillman, of New York, will speak on the subject of "Backward Traction in Caries of the Spine."

"THE PROCEEDINGS OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS."—This monthly publication, it is announced, will be discontinued on the completion of its eighth volume. We trust that the proceedings of the society will be published in some form, for in the past they have been of great value.

THE NEW YORK SKIN AND CANCER HOSPITAL.—We learn that Dr. James B. Hunter has resigned his position on the staff of the hospital, and that a new hospital has been organized under the title of the New York Cancer Hospital.

THE GALLIGO PRIZE has been awarded by the Medico-Physical Society of Florence to Dr. A. Bianchi and Dr. C. Balocchi, for their memoir on "The Regressive Spinal Paralysis of Infancy."

THE ILLINOIS STATE BOARD OF HEALTH.—At the last annual meeting of the board, the officers were re-elected, as follows: The Hon. Newton Bateman, LL. D., president; John H. Rauch, M. D., secretary; A. L. Clark, M. D., treasurer. It was ordered that diplomas issued by the College of Physicians and Surgeons, of Joplin, Mo., and by the Kansas City Hospital Medical College, for the current session, 1883-'84, could not be received as the basis for certificates entitling to practice in Illinois.

ALLEGED "BURKING" IN OHIO.—According to a newspaper report, the bodies of three persons who had evidently died in consequence of violence were recently found in the dissecting-room of the Ohio Medical College, of Cincinnati, and the theory was entertained that murder had been committed for the sake of obtaining anatomical material.

THE SURGEON-GENERAL OF THE NAVY.—It is reported that the Secretary of the Navy has recommended Medical Director Francis M. Gunnell to the President for appointment as surgeon-general of the navy.

PROFESSOR FREEHOUS, according to the "Lancet," has had the grand cordon of St. Stanislaus conferred upon him by the Russian Government, in recognition of his services in connection with the education of Russian students at Breslau and Berlin.

ERRATA.—As circumstances rendered it impossible for Professor Wilder to see the proof of the first part of his second Cartwright Lecture, published in our last issue, the following typographical errors crept in, which the reader is requested to correct: For "mesen," wherever it occurs, read *meson* (the mesal or mesial plane or line). On page 206, in the paragraph numbered 2, after "concentration," for "and," read *of*. On the same page, seventh line of the paragraph headed "Lateral Hemisection of the Calva," for "1.3 cm.," read *1-3 cm.*. In the foot-note, on the last line of the same page, after "suggested," for "to," read *by*. On page 207, second column, sixth line from the bottom, the number "11" should not be italicized. On page 208, fifteenth line from the bottom of the first column, for "portacava," read *postcava* (vena cava ascendens). In the journal for February 16th, page 178, in the paragraph numbered 6, the word "mesen" should be *meson*. In the concluding portion of the second lecture, published in this issue of the journal, in the explanation of Fig. 44, for "dorso-central," read *dorso-ventral*. In the explanation of Fig. 45, for "calcareas," read *calcares*. On page 234, second column, twenty-third line from the top, for "carried," read *carred*. On page 235, first column, twenty-ninth line from the top, for "cord," read *cast*. On page 235, second column, ninth line from the top, for "fætuses of children," read *fætuses and children*.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 17, 1884, to February 23, 1884:*

PATZKI, JULIUS H., Captain and Assistant Surgeon. Leave of absence extended one year on surgeon's certificate of disability, with permission to go beyond sea. S. O. 43, Par. 9, A. G. O., February 20, 1884.

MADDOX, T. J. C., First Lieutenant and Assistant Surgeon. Assigned to temporary duty at Meyer's Springs, Texas. Per Post Orders No. 27, Par. 1, Fort Clark, Texas, February 13 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending February 23, 1884:*

NASH, F. S., Passed Assistant Surgeon. Detached from the U. S. S. Dispatch, and waiting orders.

RUSH, W. H., Passed Assistant Surgeon. Detached from the Minnesota, and ordered to duty on board the Dispatch.

HALL, J. H., Passed Assistant Surgeon. Ordered to the Minnesota.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, March 3d:* Medico-Chirurgical Society of German Physicians; Morristania Medical Society; Brooklyn Anatomical and Surgical Society (private); Utica (N. Y.) Medical Library Association.

Tuesday, March 4th: New York Obstetrical Society (private); New York Neurological Society; Elmira (N. Y.) Academy of Medicine; Buffalo Medical Association; Ogdensburg (N. Y.) Medical Association; Medical Society of the County of Hudson, N. J.

Wednesday, March 5th: New York Medico-Legal Society; Medical Society of the County of Richmond, N. Y.

Thursday, March 6th: New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.

Friday, March 7th: Practitioners' Society (private).

Saturday, March 8th: New York Medical and Surgical Society (private).

OBITUARY NOTES.

HENRY LYMAN SABIN, M. D., OF WILLIAMSTOWN, MASS.—Dr. Sabin died on Sunday, the 24th inst., in his eighty-third year. He was born in Williamstown, May 29, 1801, and received his early education in Lenox Academy and at Williams College, and was graduated from Berkshire Medical College in 1826. After practicing for a time in Chatham, N. Y., he settled in his native town, where he remained until his death. He was a member of the Massachusetts Medical Society, of which he was at one time Vice-President, a member of the Berkshire District Medical Society, an honorary member of the Medical Society of the State of New York, for many years a trustee of the Northampton Lunatic Asylum, and a member of the corporation of Williams College.

Letters to the Editor.

THE COLLEGE OF MIDWIFERY.

NEW YORK, February 22, 1884.

To the Editor of the New York Medical Journal:

SIR: I notice among the News Items a paragraph to the effect that two bills are now before the Legislature for the incorporation of the College of Midwifery of this city. The bill which was laid before the comitia had such objectionable clauses as to render it inadvisable to recommend it, and the other bill—well, the action of the board of the concern which favors it and the pamphlet which it issued render it unnecessary to say more than that the bill should be vigorously opposed. We commend both bills to the attention of the Committee on Legislation of the State Medical Society.

Very faithfully yours,

F. R. STURGIS.

WHAT IS A CONSULTATION?

PARISH, N. Y., February 11, 1884.

To the Editor of the New York Medical Journal:

SIR: Pertinent to the "code" controversy, that is settled every year at Albany and which persists in being unsettled, I would like to obtain some information upon certain questions relating to it.

1. What is a consultation?

2. What are the relations of the attending and consulting physicians to each other?

3. Is the calling of an expert for an opinion a consultation?

4. Where several physicians are called in case of an accident or emergency, is it a consultation?

Yours truly,

J. B. TODD.

FARADIZATION IN RINGWORM.

PRAIRIE DU CHIEN, WIS., February 4, 1884.

To the Editor of the New York Medical Journal:

SIR: A short time since I had a very obstinate case of ringworm on the forearm of a stout mechanic. I tried all the known remedies without success, and finally, more as an experiment than anything else, I applied the faradaic current—the handle of the positive pole at the end of the elbow, the flat electrode of the negative pole passed repeatedly over the seat of the disease. The itching, which was intense, ceased immediately, and a clear exudation, like minute drops of sweat, appeared on the surface. A second application, two days afterward, left nothing of the ringworm but desquamated skin. A mild, emollient ointment was applied between the applications of the battery.

Yours truly,

ALEX. F. SAMUELS.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of February 12, 1884.

Dr. CHARLES MCBURNEY, Vice-President, in the chair.

DISLOCATION OF THE COMMON CAROTID ARTERY.—Dr. F. LANGE presented a patient, a woman forty-seven years of age, who had been troubled with a disagreeable feeling in her throat for about nine months, which she described as a perpetual desire to swallow. She had been treated with internal remedies and external applications, and called at his office about a week ago, when he examined the throat and discovered, what could be readily seen on the posterior wall of the pharynx on the right side at the lower edge of the arcus pharyngo-palatinus, a roundish pulsating tumor. Closer examination showed that it was the common carotid artery, which was dislocated and could be traced by laryngoscopic examination as far down as the arytenoid cartilage.

There were also hypertrophy of the left ventricle, a decided thickening of the coats of the other carotid artery, which was abnormally superficial, and some albumin in the urine. The patient said that about nine years before she had an attack of acute nephritis. The question was, whether the trouble depended upon the anatomical abnormality, and had always existed, or only since the trouble in her throat had been manifested.

On the left side the soft parts were slightly prominent, and were sunk in on the right side. Dr. Lange thought the prominence on the left side was due to the superficial position of the common carotid artery. Moreover, the entire larynx seemed to him to be abnormally movable, especially so as on the right side one could pass the fingers behind the thyroid cartilage and pull the artery out, dislocate it laterally, and push the larynx well over to the opposite or left side. He thought it probable that it was the common carotid and the beginning of the internal carotid which were dislocated. The artery seemed so movable beneath the mucous membrane of the pharynx that, by some pressure from the right side, it could be pushed almost as far as the middle line, passing from there upward and to the right side in a curved line.

ARTHRITIS DEFORMANS OF THE KNEE; HYDRARTHROSIS; CORPUS MOBILE; ARTHROTHOMY.—Dr. LANGE also presented a patient with the following history: A man, fifty-eight years of age, had been troubled with his right knee for a good many years, and attributed it to a very curious cause. For more than fifteen

years he had suffered from a constant feeling of pressure in the region of the rectum, which obliged him to use the *pot de chambre* very frequently. At length he fell into the bad habit of yielding to this sensation so frequently that for the greater part of the day he was seated on a small pot, which he used to carry with him. The most thorough examination failed to reveal any material change about the rectum to account for this suffering, and Dr. Lange took it to be a symptom of marked hypochondriasis, which of late, by mere force of the will, had been decidedly improved. The patient thought that this constant low-sitting posture, with the consequent great flexion of the knees, and more especially the right one, had been a great strain upon the latter. After a time it became thickened and abnormally movable, although it did not prevent him from walking, unless he used it for a long time continuously. When Dr. Lange saw the man, last August, his right knee presented really a grotesque appearance. With one exception, it was the largest knee joint he had ever seen; in circumference it exceeded its fellow by 20 cm. This was due mostly to fluid within the capsule. The latter was much thickened, and so distended that its upper margin reached almost to the middle of the thigh. In the popliteal space there was a protuberance about as large as a medium-sized fist, surmounted by a smaller protuberance as large as a small apple, resistant and smooth, and situated above the external condyle. The leg was somewhat oedematous, and the subcutaneous veins were distended. Flexion and extension could be made almost to the natural degree. Besides, there was lateral mobility to such an extent that at each step the knee was very decidedly projected outward, and a pronounced genu varum set in. It was to be seen now that this abnormality was still present if the patient removed the apparatus.

Dr. Lange performed arthrotomy in September, making two long lateral incisions. A large amount of synovial fluid escaped, and such an enormous mass of soft fibrous layers that he did not think it could have amounted to less than a pint. They were mostly scraped out by means of a sharp spoon, leaving the synovial membrane thickened, smooth, velvet-like, and highly vascular. Together with these masses, a bony body escaped, of about the size of a large bean, rough on the surface—bony but covered by a very thin layer of cartilage, as was to be seen on section. The bony and cartilaginous structures of the joint presented the characteristic changes of arthritis deformans. There were depressions and elevations on the cartilages, and the edges of the bones were thickened and broadened by irregular pad-like protuberances. The swelling in the popliteal region was hardly affected by the incisions in front, and became only a little smaller. Dr. Lange would have incised that also, but, contrary to his expectation, the man had lost a great deal of blood, mostly from the highly vascularized and thickened synovial membrane, so that he was obliged to desist from further surgical interference for the time being. Drains were inserted, the wounds were closed with sutures, and the knee was immobilized, of course, over an antiseptic dressing. For the first few days the discharge of synovial fluid was so copious that the dressing had to be changed almost daily, but healing took place without any bad symptoms within about four weeks. The size of the knee had been reduced considerably—according to a measurement taken two months after the operation, by about 18 cm. At present it measured 42 cm., which was 12 cm. less than at the time of the operation. The swelling in the popliteal space was also decidedly smaller and softer, and, on motion, a soft crepitus was to be felt in it here and there, as if fibrous bodies escaped under the pressure of the finger. Thus far, the abnormal lateral mobility had not been improved. The patient was now wearing a very solid and strong splint reaching from the pelvis to the shoe, and at the same time counter-pressure

was exerted upon the outer side of the leg immediately below the knee, to counteract the tendency to outward subluxation of the tibia. It seemed as if there had been some loss of bony substance at the inner condyles, so that a wide gap was formed between them when the leg was forced into a straight position. Dr. Lange's idea was to maintain this position with the splint, thereby causing pressure of the external condyles against each other, and gradual loss of bony substance, until both surfaces could meet again to such an extent as to make the adaptation perfect. Perhaps complete ankylosis would be the most favorable result for the patient. There was neither any abnormality of sensibility or of function of the sphincters, which could warrant assuming a spinal origin of the affection.

ADDUCTION AND ABDUCTION IN FRACTURES OF THE NECK OF THE FEMUR.—Dr. W. S. HALSTED presented a patient with fracture of the neck of the femur with adduction, and a specimen of intra-capsular fracture of the neck of the femur from a case in which there had been adduction and a quarter of an inch shortening. He called attention to the necessity of making allowance for adduction and abduction in the estimation of the amount of shortening in these cases. From certain measurements made upon dead and living subjects, he had demonstrated that, as abducting the lower limb made it measure less along the line from the anterior superior spine of the ilium to either malleolus, so adducting it made it measure more along the same line; furthermore, that, one leg being adducted, the other must be adducted to be brought parallel with it. Hence, in a fracture of the neck of the femur with adduction, the injured limb might actually measure more than the sound one—*First*, because it was lengthened by adduction; *second*, because its fellow was shortened by abduction. In the case from which his specimen had been taken he had been able to make the diagnosis of fracture, because of the recognition of these facts. The injured limb was *apparently* shortened, but, by measurement from the anterior superior spine to the malleoli, was one eighth of an inch lengthened, although a quarter of an inch shortened along Bryant's line. The patient presented with fracture of the neck of the femur and abduction had limbs of apparently equal length. Along Bryant's line the injured limb measured three eighths of an inch, but from the anterior superior spine of the ilium to the malleolus externus an inch and a quarter, shorter than the sound one. Dr. Halsted remarked, further, that, in cases in which, measured on Bryant's line, there was equal shortening, the adducted limbs would render more of a limp necessary than the abducted ones. In consideration thereof, he believed it unwise to allow the limb to remain in an adducted position.

Dr. ALFRED C. POST remarked, with regard to the anatomical specimen, that it hardly seemed probable that such a degree of absorption could have taken place within two weeks unless there had been some before. The specimen itself would seem to indicate that several months must have passed after the receipt of the injury.

Dr. HALSTED said the man asserted that he had never had any trouble about his hip joint, and had neither been obliged to walk with a limp nor received any injury.

ANEURYSM OF THE FEMORAL ARTERY; LIGATION OF THE EXTERNAL ILLAC; CURE.—Dr. McBURNEY presented a patient with the following history: A man, fifty-seven years of age, ten years ago received a slight injury over the right femoral artery high up, and, apparently in consequence of that, a tumor formed, which had slowly but steadily increased in size, when, at the end of that time, he came under Dr. McBurney's observation. The patient had not had any pain or inconvenience from the tumor, but, on account of its rapidly increasing growth of late, he sought advice, and in November last came under Dr. McBur-

ney's care, who found a pulsating tumor in Scarpa's triangle, which presented the usual features of an aneurysm.

Dr. McBurney applied digital compression; but the patient was not prepared at that time to submit to treatment, and returned to his home in Vermont. After doing considerable hard work, he returned in December, and, when Dr. McBurney then saw him, he found Scarpa's triangle almost entirely occupied by the tumor, which also extended outward as far as the external edge of the great trochanter. It pulsed throughout its entire extent. He thought there still was room above the tumor to apply digital compression, which method was faithfully applied continuously for twelve hours by Dr. Woodward and other members of the house staff, but without avail. He then, on December 20th, ligated the external iliac artery. The operation was performed in the usual way. One noticeable feature about the case was that the vessel was so tortuous that it descended below the pelvis as much as an inch and a half, and had to be drawn up in order to throw a ligature about it. The operation was performed under frequent irrigations of bichloride solution, and a catgut ligature was used, which was applied about two inches above Poupart's ligament. The gut was an E violin-string, prepared and given to him by Dr. Briddon. The iodoform-gauze dressing was applied, and the first dressing was allowed to remain six days. At the end of that time it was removed, and the wound was found entirely healed, except where the drainage-tube had been inserted. A new dressing was applied, which was removed four or five days afterward, and the subsequent progress of the case was favorable and entirely uninterrupted. Nothing occurred after the operation in the way of interference with the circulation, such as sometimes manifested itself in cutaneous lesions. Dr. McBurney had not been able to find any pulsation or bruit in the tumor since the operation. It had diminished in size somewhat, but just how much he was at the time unable to say. It was nearly eight weeks since the operation was performed, and it seemed to him to be a satisfactory cure.

THE GEOGRAPHICAL DISTRIBUTION OF URINARY CALCULUS, WITH AN INQUIRY INTO ITS CAUSE.—Dr. E. L. KEYES then read a paper on this subject. [See page 237.]

Dr. Post said that he had lately received a letter from his son, in Beirut, Syria, in which he stated that he had just performed his two hundred and first operation for stone, showing that stone was very prevalent in that region including Syria and the adjacent provinces. All these operations had been performed within fourteen years. There were other operators in that locality, but most of the operations had been performed by Dr. Post, and probably also chiefly in hospital service. The climate was a semi-tropical one.

AN ARRANGEMENT FOR HOLDING NEEDLES AND SILK was shown by Dr. LANGE, who remarked that it might commend itself for very fine needles, such as were used for suture of the intestine, as it was rather tedious to arm the needles during the operation. The needles were to be threaded and secured between two rubber bands (of disinfected drainage-tube) around an ordinary test-tube, and the ends of the silk around the other extremity with another rubber band; then the whole was to be immersed in an ordinary lamp-chimney filled with pure glycerin, and corked with rubber corks. Thus far the needles had not corroded when kept in pure American glycerin, nor had he noticed that the sulphur which the rubber mostly contained had tarnished them.

COMPOUND DISLOCATION OF THE FIRST PHALANX OF THE GREAT TOE.—Dr. J. C. HUTCHISON had been called to see a man who had fallen from a tight rope. He visited the patient within half an hour after the accident, and found that he had a compound backward dislocation of the first phalanx of the great toe.

The wound was on the inner side, communicated with the joint, and was about half an inch in diameter. All the usual expedients were resorted to for effecting reduction, but without accomplishing it. He then divided the internal lateral ligament, a portion of which seemed to have been torn. Subsequently he divided the external lateral ligament, but still was unable to reduce the dislocation. He then divided the tendon of the extensor proprius pollicis subcutaneously, and at once was able to put the bone into position. No splint was used, but the toe was simply enveloped with a considerable quantity of cotton wool, and surrounded with a bandage. At the end of three or four days the dressing was removed and reapplied. Dr. Hutchison saw the patient walking with a crutch about a week after the occurrence of the accident, and learned that he had a satisfactory recovery. The case was interesting to him because it was the only one which he had met with, and it was also one which illustrated the difficulty of reduction, the same that was observed in dislocations of the thumb.

Dr. McBurney asked if the extensor tendon of the toe seemed to be the resisting point.

Dr. HUTCHISON said it seemed so, and he had an impression that, if he had divided this tendon first, reduction could have been effected without further operative interference.

NEW YORK MEDICAL AND SURGICAL SOCIETY.

Meeting of December 22, 1883.

Dr. T. M. MARKOE chairman for the evening.

DIETETIC TREATMENT OF PNEUMONIA.—Dr. B. W. MCCREADY said that he had been called about three weeks before to see a maiden lady, seventy years of age, who had previously been under his care. Dr. Hubbard had been called to see her at night, and had found her suffering very much from difficulty about the chest, and apparently dying. Dr. McCready arrived in the morning, and found the breathing near 50 a minute, the pulse 140, large mucous râles over the entire chest, and bronchial respiration at the root of the lungs. She expectorated with a great deal of difficulty. The sputa were of a blackish-brown color. She could not speak, and could scarcely swallow. Nourishment and stimulants were given as best they could be, and she continued to live for six days. Her sister, a slender, pale maiden lady of sixty years, came to nurse her, and was taken down in a similar manner and sent home. When Dr. McCready arrived she was breathing very rapidly, was not able to speak more than a word or so at a time, and had constant cough. There were large mucous râles over the entire chest. She received wine-when and milk for nourishment. A slight amount of counter-irritation, as much as her delicate condition would permit, was made over the chest. On the third day a moderate bronchophony was detected at the summit of the left lung, along with some dullness. The mucous râle obscured the crepitation entirely. Scarcely any medicine was administered; she took a little more than a pint of milk in the twenty-four hours, together with two or three eggs, a small amount being administered every four hours. She lay between life and death for some time, but at the end of a week began to convalesce, and was now feeling quite well. Dr. McCready attributed recovery to the systematic way in which nutrition was kept up, and to good nursing. While certain of the ordinary signs of broncho-pneumonia were masked, it was evident that such was the form of disease from which the patient suffered. He believed that nourishment administered at intervals of two hours, as was often done, was too frequent, as the stomach had not time to digest one meal before another was taken. He found that patients took milk better with a little carbonic-acid water than with lime-water.

THE POSSIBLE RELATION OF MYXEDEMA TO ABSENCE OR DISEASE OF THE THYROID GLAND.—Dr. A. B. BALL would allude for a moment to a point of interest with regard to the etiology of the disease known as myxœdema. In a recent discussion at the Clinical Society of London, Dr. Felix Semon had stated that an important contribution to the etiology of myxœdema had come from a very unexpected quarter. Professor Kocher, of Berne, Switzerland, during the past few years had extirpated the thyroid gland, either partially or wholly, in one hundred and one cases of disease of that organ. One of these cases, operated upon in 1874, had since that time been under the observation of another physician, who had recently called Professor Kocher's attention to the peculiar condition of the patient. Symptoms had developed which resembled very closely those of what was known as sporadic cretinism. The question arose at once whether the operation had had anything to do with this condition, and Professor Kocher set about examining as many of the other patients whom he had operated upon as could be found. For various reasons, only thirty-four could be examined. In sixteen of these cases only a portion of the thyroid body had been removed, and in all of them the general health had been preserved. Of the remaining eighteen cases in which the gland had been totally extirpated, there were only two of the patients who continued to be in good health. In one of these a small accessory thyroid gland had become hypertrophied, and in the other case a return of the goitre had occurred. All of the other sixteen cases of total extirpation presented a bodily and mental condition closely resembling that seen in sporadic cretinism and myxœdema.

The number of cases was sufficiently large to render it highly probable that the connection between the removal of the thyroid body and the development of the cretinoid condition was not accidental, but rather was truly causal. This interesting observation of Professor Kocher's naturally suggested the question whether the condition of the thyroid gland did not play an important part in the development of myxœdema. With reference to this point, Dr. Ball had recently examined a patient with typical myxœdema, who had been under his observation for the past ten years, and ascertained the following interesting particulars: When pregnant with her first child, about twenty years ago, the patient became affected with goitre sufficiently large to cause disfigurement and occasion her much anxiety. Her physician, the late Professor C. R. Gilman, assured her that the tumor would disappear after her confinement, and this result did occur. Her present symptoms of myxœdema, which were of the most pronounced character, began to develop gradually not very long after this time. At present no trace of the thyroid body could be detected.

AORTIC ANEURYSM BURSTING INTO AN ADHERENT PERICARDIAL SAC; OBSCURE SYMPTOMS.—Dr. G. G. WHEELLOCK narrated the following case: The patient, a colored woman, thirty-nine years of age, was admitted to the hospital on October 20th. She had been in the hospital some years since suffering from rheumatic troubles. At this time she complained chiefly of pain in the chest beneath the sternum, running through to the back, and of a great deal of dyspnoea and palpitation. The heart was found to be much enlarged, beating rapidly, and a loud diastolic murmur was heard at its base. His attention was called to the patient on the 5th of November, as she had had an attack of syncope during the night. She was then suffering intense pain, radiating through the chest to the back, and seemed to be much cyanosed; the pulse had increased in frequency to 140 beats, and an entirely different murmur had developed at the seat of the old one, systolic in character, heard distinctly all the way down toward the apex. The seat of greatest intensity was at the junction of the left third rib with the sternum. It was not

transmitted into the aortic region toward the right; at the locality mentioned there were also a perceptible thrill and pulsation. Three possible theories suggested themselves in explanation of her condition and physical signs. First, that endocarditis had developed and caused a new murmur. The absence of rheumatic symptoms and of febrile action was opposed to this view. Second, that there had been rupture of one leaflet of the mitral valve, permitting regurgitation from the ventricle back into the auricle, causing over-distension of the latter with attending impulse and murmur. The locality was somewhat opposed to this view, as the left auricle was deeply seated and rather more to the left. The third possibility was aneurysm. Opposed to this view was the fact that the murmur was not in the least transmitted to the right, and, had the rupture taken place suddenly within the pericardium, death would have followed speedily by paralysis of the heart by pressure. The patient lived five days longer, growing steadily worse until death. During this time the murmur continued systolic, accompanied by thrill and impulse. She complained of dysphagia, and of great pain extending from the sternum at the seat of the thrill to the vertebral column. She denied venereal disease.

At the autopsy, the pericardium was found totally adherent, so that there was no pericardial sac whatever. The mitral valve was considerably narrowed and stiffened, the aortic very much so. The aorta itself was the seat of atheromatous degeneration. About a quarter of an inch above one of the cusps, on the right side of the vessel, was a clear cut opening through the aorta, about half an inch in length and a quarter of an inch in breadth. The opening led into a cavity of the size of a small apple. The cavity was situated above and to the left of the right auricle, and its walls were formed of the pericardium externally and of the heart substance internally. Next to the walls were tolerably firm clots, and centrally there was a soft recent clot. The heart, with the pericardium, weighed twenty-one ounces. The opening had the appearance seen in gastric or intestinal ulcer with rounded edges, as if punched out. After the rupture had occurred, the blood had apparently dissected off the adherent pericardium sufficiently to make a place for itself and then formed a false aneurysm. All the remaining portion of the pericardial sac was closed by old adhesions. This anomalous condition of affairs sufficiently explained the nature of the accident which gave rise to the attack five days before death, and showed ample reason for the difficulty in making a positive diagnosis.

The CHAIRMAN thought the case an interesting one from a pathologico-anatomical point of view. Aneurysms occurring in this situation were comparatively rare, and never reached a large size before rupture of the coats took place, chiefly because the aorta within the pericardium had an external or fibrous coat. In the case narrated by Dr. Wheelock, however, the usual pathological process was modified by extensive adhesion of the pericardium to the organs which it inclosed. He once had a case of this form of aneurysm in a patient who, on rising in the morning, fell dead a few steps from the bed. In this case the aneurysm had developed within and ruptured into the pericardium, so that when the heart contracted the pericardial sac immediately filled with blood, and expansion was impossible. The patient died instantly.

Dr. ROBERT WATTS reported a case of inversion of the uterus by a fibroid tumor. [Printed elsewhere in this journal.]

THE PREVENTION OF OOOZING AFTER THE USE OF EMSARCH'S BANDAGE.—Dr. A. C. POST said that, by adopting the method of applying the dressing with some degree of firmness before removing the Emsarch bandage in bloodless operations, he had been able to avoid the troublesome oozing which often occurred when the bandage was removed before dressing the wound. In

operations upon the limbs, all oozing might be prevented by following the method mentioned and by keeping the limb elevated for three or four hours, except when large vessels were divided.

Dr. SANDS and Dr. WEIR testified to the value of the method, which was first suggested by Esmarch himself.

ALALIA IN CHILDREN.—Dr. POST had occasionally seen cases of mutism in young children sufficiently old to speak, but he had not been able to follow them up to learn the ultimate result except in one instance; in this the child reached its fourth year before it finally gained the power of speech. In a patient six years old, seen at his clinic the day of the meeting, hearing was good, and the mental faculties seemed unimpaired, but the child could scarcely utter any words except "papa" and "mamma."

Dr. WATTS recalled one case in which the power of speech was not manifest until the fourth year. At present, at the eighth year, the child could talk perfectly well.

Dr. SANDS had seen as many as half a dozen cases, in all of which there was want of proper mental development.

The CHAIRMAN was of the impression that there were a good many cases in which speech was defective up to four or five years of age. He recalled two cases in one family. Both persons had since grown up to healthy manhood and womanhood, and showed no lack of mental or physical development.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of January 2, 1884.

A FURTHER NOTE ON THE SPECIFIC TREATMENT OF ENTERIC FEVER.—Dr. JAMES C. WILSON read the following paper:

A year ago I read before the College a brief paper "On the Management of Enteric Fever" according to a plan based upon the so-called Specific Treatment. That communication, which will be found in the sixth volume of the third series of the "Transactions," beginning on page 221, was the outcome of the clinical study of a very limited series of cases in which the plan referred to had been fully carried out. The object of the present communication is to lay before you the results of the plan as employed during another year in the management of a second series of cases.

Before presenting to your attention the facts relating to this second series of cases, permit me to state that the plan of treatment consists in a close adherence to the so-called rational or expectant method of treatment in all its details, plus the systematic use of purgative doses of calomel in the early days of the attack, and of iodine and carboic acid throughout its whole course. These drugs are administered chiefly with the intention of realizing their effects in diminishing the activity of the supposed specific cause of the disease, and the treatment is therefore properly designated a specific treatment in contradistinction to the rational or expectant treatment on the one hand, and to all forms of symptomatic treatment on the other.

The first series of cases numbered sixteen, and all the patients recovered. The second series, treated during the year 1883, by a curious coincidence, also numbered sixteen, and two of the patients died. Of these, seven were severe, the temperature reaching or exceeding 104° F. (40° C.).

Of these seven severe cases, the two which terminated fatally were in colored men, admitted to the wards of the Philadelphia Hospital late in the attack and in a state of profound stupor. One, aged twenty-seven years, died on the seventh day after admission; the other, aged forty-seven years, on the twenty-first day. The latter passed albuminous urine, and presented after death the lesions of interstitial nephritis in addition to those of enteric fever.

Two non-fatal cases were attended by profuse and repeated

intestinal hemorrhage in the third week. One of the patients, a man aged twenty, had, during convalescence, necrosis of the mastoid process of the right temporal bone. One case of great severity occurred in a man aged sixty-two years, whose convalescence was, however, rapid and without sequels. No instance of relapse was observed. The characteristic eruption was present in all the severe cases. It was not discovered in four of the mild cases.

The average duration of the five severe cases, in which recovery took place, was about thirty-two days; that of the nine mild or medium cases was about twenty-four days. Of the whole number, six were treated in hospital and ten in private practice.

It is worthy of notice that the convalescence in these cases was rapid, as a rule without complication, and that no instance of relapse occurred. An analysis of the combined series shows as a result of this treatment in my hands thirty-two cases—sixteen treated in hospital, sixteen in private practice, with two deaths (patients admitted to hospital in profound stupor). The death-rate is therefore 6.25 per cent. I refrain from citing, for comparison, the familiar statistics of the death-rate of enteric fever. We have come to regard it as ranging from 15 to 20 per cent., with a more favorable showing in private than in hospital practice. But Welch, from the statistics of the medical service of the British army, has recently shown it to exceed 33.3 per cent., and Dr. Francis Delafeld, in an important statistical paper on this fever as it occurs in New York (see "Medical News," November 24, 1883), has shown that the death-rate in hospital cases, though varying in different years, ranges between 20 per cent. as the lowest and 30 per cent. as the highest limit.

Dr. ARTHUR V. MEigs said: This so-called "Specific Treatment of Typhoid Fever" appears to me a mistaken plan founded upon an untenable theory. We are asked, in the first place, to assume that typhoid fever has for its cause a germ whose very existence is not known, and, second, that calomel, iodine, and carboic acid, given by the mouth, will meet with and destroy this imaginary germ. Neither of these assumptions can be considered proved. Why do we not give the same drugs in cases of scarlet fever, measles, or small-pox, for there is as good reason to believe them to originate from germs, and that the same germicides would be effective for their destruction? I should not be so outspoken in my denunciation of this method of treatment if it could be looked upon as harmless, but it seems capable, on the contrary, of much mischief. Whatever may be the effect of such large doses of iodine and carboic acid, we were almost all taught, and have up to this time believed, the effect of purges given in the earlier stages of typhoid fever to be most disastrous. Dr. Wilson himself, I doubt not, was taught, as I was, when a resident physician in the Pennsylvania Hospital, that even a teaspoonful of castor-oil given to a patient in the early stage of the fever might cause a diarrhoea which would continue throughout the attack. Is there no reason for this belief, and is not calomel capable of producing the same effect? Dr. Wilson says the treatment of typhoid fever is at sea; to me it seems, on the contrary, that there is no disease in regard to the treatment of which there is such general agreement. How many men in this room treat cases of scarlet fever alike, and how many treat typhoid fever differently? The present treatment of the disease is the treatment of common sense; so far as the local lesion is concerned, we treat it as a surgeon treats a wound: we try to give the part rest and avoid all causes of irritation, and nature thus is given time and opportunity to heal the ulcers. We treat symptoms as they arise, and support the strength of the patient with food and water, and stimulants if necessary, through the four or six weeks during which fever is burning his tissues until he is reduced almost to a skeleton.

Now, can purging with calomel or administering such nauseous drugs as carbolic acid and iodine conduce to this result? Will the patient be any better able to go through his weeks of fever? Does Dr. Wilson show that the method shortens the duration of the disease one day or one hour? It appears like asking us to go back to the days of ignorance which existed before Stokes and Graves and the great men of that day who taught us how to treat the disease. Years ago Stokes put in a few words the common-sense view of the question. It must be remembered that at that time the distinction between typhus and typhoid fevers was not drawn. He says: "I confess that it was not until several years after I commenced practice that I became fully aware of the erroneousness of what is termed the anatomical theory of disease; and I feel certain, humiliating though the confession may be, that the fear of stimulants in fever with which I was imbued was the means of my losing many patients whose lives would have been saved had I trusted less to the doctrine of inflammation and more to the lessons of experience, given us by men who observed and wrote before the times of Bichat or of Hunter.

"The hospital physician will be frequently asked by students to state the principle on which he administers wine in fever. Typhus fever is a disease which has a tendency to a spontaneous and favorable termination, but one in the course of which the powers of life are attacked by a most malignant influence. By wine, food, and other stimulants we support nature until the struggle is past, so that, to use the words of an ancient author, which embody a more profound principle than appears at first sight, we 'cure the patient by preventing him from dying'—that is to say, we prolong his existence until the natural and favorable termination of the disease arrives. We do not allow our patients to die of exhaustion, and, bearing in mind the depressing influence they have to struggle with, we give stimulants at the proper time and with a bold hand. We give our patients an artificial life till the period arrives when nature and health resume their sway."

If we are asked to try the method because it lessens the death-rate, I think that can hardly yet be considered as proved. The number of cases recorded by Dr. Wilson is yet too small to prove any point. In looking over some old lectures by my father, the late Dr. J. Forsyth Meigs, delivered about the year 1850, I found that he reported a series of sixty-nine cases treated in private practice and only five deaths. This makes a death-rate of 7.24 per cent., while Dr. Wilson's series of thirty-two cases and two deaths makes the death-rate 6.21 per cent. The number of cases treated by him is less than half. The cases reported by Dr. Meigs were treated when bleeding and purging were still customary, and even his results are but little inferior to those of Dr. Wilson, and both are infinitely better than any published hospital statistics. In the first thirty-nine of Dr. Meigs's series of cases he had four deaths; but, in the thirty coming afterward, only one death occurred. These results bear comparison with Dr. Wilson's, particularly the second series, which came after the first, and when bleeding and purging were becoming less the medical fashion of the day and the expectant plan was more pursued. A comparison of the first and second series of cases shows how little reliance is to be placed upon deductions drawn from the treatment of such small numbers; for in the first the death-rate was 10.25 per cent., while in the second it was only 3.33 per cent. An examination of such records as I possess enables me to recall twenty-seven cases I have treated in private practice. In these, two patients died, making a death-rate of 7.40 per cent. One of the deaths was of a boy, who was taken sick in a house where there were eight or nine cases of diphtheria and diphtheritic sore throat, almost every one living in the house at the time being more or less affected—

the cause being a foul, leaky brick drain which ran through the cellar. The other death was of a man, about fifty years of age, in whom the diagnosis was not made until about the end of the second week of the disease. During the first two weeks he was in and out of bed, and made at least two journeys of sixty or seventy miles by rail, and finally died of perforation of the bowel and peritonitis, which were found at a post-mortem examination. If the total number of cases reported by Dr. Meigs and my own be considered together, there were treated in private practice ninety-six cases with seven deaths, making an average death-rate of 7.29 per cent. Not a bad showing for the old treatment, when it is considered that typhoid fever has always been looked upon as one of the most fatal of all diseases.

Reports on the Progress of Medicine.

ANATOMY AND PHYSIOLOGY.

BY GRAEME M. HAMMOND, M.D.

THE INNERVATION OF THE MAMMALIAN HEART.—L. C. Woolridge, D. Sc., and Mr. George Henry Lewes ("Proc. of the Royal Soc.") state that the ventricular nerves, which are very numerous, form the greater part of the nervous connection between the auricle and the ventricle. They can not be adequately stimulated after they have passed on to the ventricle, since the stimulus affects the heart itself and destroys the activity of the ventricle by bringing about a peculiar condition of fibrillar contraction. The ventricular nerves pass on to the ventricle at definite points of the auriculo-ventricular boundary, where they are collected into larger trunks. Division of these trunks neither influences the rhythm of the heart nor impairs the action of the vagus or accelerans nerves. The ventricular nerves are the continuation of certain definite cardiac nerves, which can be isolated in the thorax at a distance from the heart. The majority of the nerves on the posterior surface of the heart are derived from a trunk which arises either from the left vagus ganglion, or from some part of the ansa Vieusseni (left accelerans). This nerve usually runs quite isolated to the heart. Stimulation of its peripheral end resulted as follows: Out of fourteen experiments, it exerted in four a vagus action, without any acceleration; in two an accelerating action, without any inhibition; in eight it had no influence on the rhythm. The nerve sometimes gives off branches to the auricle; in some of the cases, where no influence on the rhythm was noticed, these branches had been cut away. Stimulation of the other cardiac branches, which are in connection with the ventricular nerves, sometimes produced inhibition and sometimes acceleration. Division of the trunks which continue these nerves on to the ventricle did not produce any change in the result of their stimulation. It is therefore concluded that the ventricular nerves have no direct influence on the rhythm of the heart. Stimulation of the central end of those cardiac nerves which are continued on to the ventricle is marked by a rise and fall of blood pressure, and slowing and quickening of the pulse.

THE INFLUENCE OF THE INORGANIC CONSTITUENTS OF THE BLOOD ON THE VENTRICULAR CONTRACTIONS.—Dr. Sidney Ringer ("Journal of Physiology," August, 1883) has found that, when fed with a neutral fluid, the ventricle will contract for ninety minutes or longer. Bicarbonate of sodium added to a saline solution increases the ventricular contractions. This is probably due to its alkaline properties, as ammonium carbonate or lime-water will produce the same restoration of the beats. It is more than probable that the acid developed in the muscles under con-

traction gradually weakens, and at last suspends contractility. The alkaline solution neutralizes the acidity and renews the ventricular contractions.

THE COAGULATION OF THE BLOOD.—Mr. L. C. Woolridge ("Journal of Physiology," August, 1883) remarks that blood plasma, after it has left the vessels, converts the white cell into fibrin and liberates a certain substance, called fibrin ferment, which is able to bring about the coagulation of the fibrinogen in the plasma. This fibrin ferment owes its power of coagulation to the presence of a substance called lecithin, a body omnipresent in protoplasm. Lecithin is prepared by making an alcoholic extract of the lymph cells.

THE PROPAGATION OF HEAT BY CONDUCTION IN BONE, BRAINTISSUE, AND SKIN.—Dr. J. S. Lombard ("Proc. of the Royal Soc.," June, 1882) gives the results of over seven hundred experiments performed by placing one surface of the object to be tested in contact with water at a known temperature, and the other surface with thermo-electric piles connected with a galvanometer. One degree of the galvanometer equaled 0.0006742° C. Water 0.1° C. colder than the atmospheric temperature was used. The tissues tested were pieces of sheep's skull and brain, each 7.5 mm. thick, and a piece of sheep's scalp 3 mm. thick. The galvanometer indicated the transmission of heat through skin in 17.6 seconds, through bone in 28.4 seconds, and through brain in 30.88 seconds. When skull and skin were taken together, the galvanometer averaged 2.767° in 1 minute, 15 seconds. When skull, skin, and brain were used together, the average deflections of the galvanometer were 0.392° in 1 minute, 15 seconds.

THE STRUCTURE OF THE CEREBRAL CORTEX.—M. J. Luys ("L'Encéphale," March-April, 1883) states that the gray substance is composed of: 1. Nerve cells of different dimensions. 2. Nerve tubes. 3. Interstitial connective tissue called neuroglia. 4. Capillaries. The nerve cells are generally pyramidal, they are yellow in color, and measure from 10 μ to 50 μ . The largest cells are found in the deepest regions of the cortex and the smallest near the surface. These cells present numerous prolongations from the apex, base, and sides. Those from the apex are continuations of the nerve cells themselves, and are prolonged into filaments, which either connect with cells in a superior altitude or else are lost in the neuroglia. Those emerging from the sides of the cells divide into minute branches and connect with branches of other cells of the same altitude. The neuroglia is constituted by an excessively fine reticulum of connective tissue, which, acting as a cement, holds the cells and nerve tubes in position. The capillaries, protected by a sheath, penetrate directly into the gray substance and divide into numerous fine branches. Their walls are adherent to the neuroglia.

CEREBRAL LOCALIZATION.—Mr. Seymour J. Sharkey ("Lancet," Oct. 13, 1883) cites the following six cases in which the autopsy revealed softening and destruction of different areas of the cerebral cortex: *Case I.*—Crural monoplegia, the lesion involving the paracentral lobule and the upper part of the ascending frontal and parietal convolutions. *Case II.*—Brachial monoplegia, the lesion occurring in the middle of the ascending parietal convolution. *Case III.*—Facial monoplegia and aphasia, the lesion being situated in the inferior extremities of the two ascending and the posterior part of the third frontal convolutions, on the left side. *Case IV.*—Paralysis of the arm and face on the same side of the body, the lower half of the cortical motor zone being the seat of softening. *Case V.*—Paralysis of the arm and leg on the same side of the body, the lesion affecting the upper part of the ascending frontal and parietal convolutions. *Case VI.*—Paralysis of one lateral half of the body, excepting the face, the lesion being found in the upper half of the motor zone. Cases III, IV, and VI agree with the observations al-

ready made by Charcot and Pitre relative to the location of the lesions accompanying the symptoms previously mentioned, but Cases I, III, and V involve a much greater area than these authors allow. Ferrier's plan of the cortical motor centers covers these three cases more exactly.

THE MOTOR ROOTS OF THE BRACHIAL PLEXUS, AND THE DILATOR NERVE OF THE IRIS.—Dr. David Ferrier ("Proc. of the Royal Society," May 10, 1883) states that the anterior division of the second dorsal nerve in the monkey invariably gives off a communicating branch to the first dorsal nerve. Dr. Allen Thomson found such a communicating branch in the human subject in twenty-seven out of thirty-seven dissections. If a perfect homology existed between the roots of the plexus in man and in the monkey, the second dorsal root would be the one presiding over the intrinsic muscles of the hand.

In investigating the subject of the dilator nerve of the iris, the spinal nerves were exposed, the posterior roots were cut, and the anterior roots stimulated, while the eyes were carefully observed. Dilatation of the pupil invariably occurred on stimulation of the second dorsal root. Stimulation of the other roots produced no change in the iris. The general result of these experiments is to show that in the monkey, and presumably also in man, the dilator fibers of the iris contained in the cervical sympathetic are derived from the anterior roots of the second dorsal nerve.

THE FORMATION OF URIC ACID IN THE ANIMAL ECONOMY, AND ITS RELATION TO HIPPUIC ACID.—Dr. Alfred Baring Garrod ("Proc. of the Royal Society," February, 1883) shows that in the semi-solid urine of birds and reptiles and invertebrata the urate is always in the form of spherule aggregates, made up of a great number of smaller spherules, each of which is united with or contained in a cell of colloid matter. Uric acid is not, as is commonly supposed, formed in the animal body during the progress of metabolism, then thrown into the blood and afterward filtered or strained off by the kidneys, and thus finally eliminated from the body; but it is absolutely found in the renal organs themselves by the action of peculiar cells. It probably exists in these cells as the urates of an organic base yielding ammonia, or as a complex organic principle, readily splitting up into uric acid and ammonia. For the most part, it is excreted as such urate, which, however, may be changed into urate of sodium, or any other metallic urate, according as it meets with one or another salt. Probably there is always a trace of uric acid absorbed into the blood by the kidney cells, and, when its forward progress is obstructed by disease or any other cause, its absorption into the blood becomes greatly increased, and it is then converted into urate of sodium on account of its meeting with large amounts of the chloride and phosphate of that metal. It is at times deposited both in man and in the lower animals, in cartilaginous and fibrous tissues, in the form of crystallized urate of sodium.

MODIFICATIONS OF MOTILITY IN MOTOR NERVES AND IN MUSCLES.—Dr. P. C. Plugge ("Revue de médecine," December, 1883) gives the results of experiments performed by himself with aconitine on the motor nerves and muscles of frogs. These conclusions differ essentially from those obtained by Laborde and Duquesnel, who assert that the motor function of mixed nerves is not only not abolished by the physiological and toxic effects of aconite, but that it persists during all the phases and up to the period of extreme intoxication, and even for a certain time after death. Dr. Plugge, after performing a great number of experiments, concludes that aconitine and pseudo-aconitine paralyze the peripheral intra-muscular terminations of the motor nerves, and operate in this respect like curare. Here is, therefore, a complete contradiction.

The experimenter employed seven different forms of com-

mercial aconitine, the toxic properties of which diminished in the following order: Aconitine of Duquesnel, of Morson, of Hottot, of Hopkin and Williams, of Merck, of Schuchart, and of Trommsdorff. The animals selected for the experiments were frogs, and the solution was injected, by means of a Pravaz's syringe, under the skin of the back. The dose of the poison varied from one tenth of a milligramme to ten milligrammes. The nerves and muscles were irritated by an induced current, the intensity of which was regulated by the apparatus of Du Bois-Reymond. The results of the excitation, both of the nerves and of the muscles, were ascertained by means of Pfüger's myograph and Marey's recording cylinder.

Another method was to inject the poison after the circulation in one of the posterior extremities had been arrested by ligating the vessels, and again after applying a ligature to the vessels on a level with the sacrum. In all these cases it was observed that those nerves and muscles which were supplied by the poisoned blood were paralyzed, while those members in which the circulation was shut off retained their excitability perfectly.

Dr. Plugge therefore contends, notwithstanding the deductions of Laborde and Duquesnel, that aconitine, if given in sufficiently large doses, causes a complete paralysis of the motor nerves.

SOME HITHERTO UNAPPRECIATED FACTS IN THE ANATOMY OF THE VENOUS SYSTEM.—Dr. John Gray, F.R.C.S. ("Lancet," Dec. 15, 1883) calls attention to some interesting experiments by injections, which show conclusively that there is a free anastomosis of the veins of the trunk, even in parts where valves exist and might be supposed to interfere with such freedom of communication.

Wax was used as an injecting fluid, and the experiments were performed both in the human subject and in monkeys, and were invariably attended with success, provided the animals operated upon were in a healthy condition. It was shown in this manner that, if a tributary vein was injected in any part of the body, as, for instance, the internal mammary, and in any direction, either backward or centripetally, the injected fluid (if thin enough for permeation) would fill every vein throughout the body and extend into its finest ramifications. This Dr. Gray conceives to be a new fact in connection with the venous circulation. In order to prove the communication, even when the veins are apparently exposed to valvular interruption, as in the azygoids, they must be injected by two distinct methods and from different points: first, forward from an iliac, renal, or sacro-lumbar—a systemic vein; and then, after tying its trunk in another subject, backward or in a direction opposed to the natural current, from the orifice of a remote collateral—e.g., an internal mammary, or internal jugular vein. In the first, the injection will be checked by the valves at the junction of the thoracics with the intercostals, while in the second it will take a circuitous route and fill the void costal portions. The next point is that the injection, in taking this course, fills every interposing organic structure. It will traverse the lungs, the liver, the kidneys, and probably the spleen, the supra-renal capsules, and the thyroid gland.

A NEW DIVERTICULUM OF THE NASO-PHARYNGEAL SPACE.—Dr. O. Pertik ("Arch. für path. Anat. und Phys. und für klin. Med.") describes a new diverticulum situated in the naso-pharyngeal space. It was discovered in a man, about fifty-five years of age, who had died suddenly. On removing the cervical vertebrae and the tissues at the back of the pharynx, a fluctuating bilateral, symmetrical sac was observed, composed of fat and connective tissue, which projected laterally and downward over the upper part of the concave wall of the superior constrictor of the pharynx. Instruments could be passed into it from the lower

part of the nasal passage, and it was found, when examined, to be nearly filled with coagulated blood. Two similar cases are reported by Zuckerkandl and Luschka. Dr. Pertik believes that these formations are congenital, and that their effect is to alter the normal resonance quality of the voice.

Miscellany.

AN ACT TO ESTABLISH THE MEDICAL FACULTY OF THE UNIVERSITY OF THE STATE OF NEW YORK, TO REGULATE THE LICENSING OF PRACTITIONERS OF PHYSIC AND SURGERY, AND TO FURTHER REGULATE THE PRACTICE OF PHYSIC AND SURGERY.—Herewith we give the full text of the two bills that were made the subject of debate at the recent meeting of the Medical Society of the State of New York:

The Committee's Bill.—SECTION 1. On or before the first day of June, eighteen hundred and eighty-four, the Governor shall appoint the Medical Faculty of the University of the State of New York, to consist of nine members, who shall be authorized practitioners of physic and surgery in this State, but none of whom shall be connected with any medical school or college which grants the degree of M. D.; provided, that in the appointments made the representation of the several systems of medical practice recognized by the incorporated medical societies of this State shall be in the proportion of six, two, and one—that is to say, the system having the largest number of licensed practitioners to have six, that having the next largest to have two, and the remaining system to have one representative; and all persons desiring to enter upon the practice of physic and surgery in this State, after November first, eighteen hundred and eighty-four, shall, before doing so, comply with the provisions hereinafter prescribed, and obtain the license hereinafter provided.

SEC. 2. Of the nine members of the said Medical Faculty, three shall serve, in the first instance, for three years, three for four years, and three for five years; and these terms shall be severally distributed by lot at the first meeting of the said faculty. All appointments made in the faculty at the expiration of the several terms fixed above shall be made uniformly for the period of five years each. All vacancies occurring in the said faculty, from whatever cause, shall be filled, before the next semi-annual meeting of the same, by the appointment by the regents of the university of a practitioner of the system of practice that had previously been represented by the person occupying the seat so vacated, such appointments to be for the unexpired term; and, in case the several State medical societies shall nominate physicians to fill such vacancies, the regents shall appoint some one of the physicians so nominated. The regents may, for cause, remove from office any member of the faculty after due notice, and an opportunity to be heard.

SEC. 3. The said Medical Faculty shall examine all applicants for license to practice physic and surgery in this State. The members thereof shall meet at least semi-annually, and at such meetings shall faithfully examine all candidates referred to them for that purpose by the chancellor of said university, and each furnish him a report in writing of his opinion as to the qualifications and merits of each candidate, referring briefly to the degree of proficiency evinced by the applicant in the branches in respect of which he was examined by him; which opinion shall be by him denominated favorable or unfavorable. The president or secretary of the faculty shall have authority to administer oaths, and the faculty to take testimony in all matters relating to its duties, and any false statement made under an oath so administered shall subject the offender to prosecution for, and, on conviction, to punishment for, perjury.

SEC. 4. Such examination shall be in anatomy, physiology, histology, pathology, theory and practice of medicine, chemistry, surgery, obstetrics, materia medica, and therapeutics, and such other branches in the several departments of medical science as the said faculty may agree upon, subject to the approval of the regents of the university. The questions forming such examinations shall be the same for all classes

of candidates offering themselves, with the exceptions of the departments of materia medica and therapeutics, in which branches the questions for each candidate shall be prepared by the representative or representatives in the board of examiners, of the system of practice to which such candidate wishes to be licensed.

SEC. 6. The orders of the chancellor addressed to the Medical Faculty and the decision of the regents of the university in each case shall be attached to the written reports of the examiners, together with the questions of said examiners and the written answers thereto of each candidate, and shall thereupon become and forever after be a part of the public records of said university.

SEC. 6. Any person, on paying fifteen dollars into the treasury of the university, and on applying to the chancellor for the aforesaid examination, shall receive an order addressed to the aforesaid Medical Faculty, instructing them to examine the candidate at one of the regular semi-annual examinations, provided that proof satisfactory to the chancellor is first given that the candidate is over twenty-one years of age, of good moral character, and has received a diploma issued to him or her, conferring on him or her the degree of doctor of medicine from some legally incorporated medical college.

SEC. 7. The regents of the university, after finding that seven or more of the members of said faculty participating in the examination have given an opinion in favor of a candidate, shall issue to him or her a license to practice physic or surgery in the State of New York, for which license the candidate shall pay to the university the further sum of ten dollars. Said faculty may refuse to recommend a license to any individual guilty of dishonorable or criminal conduct, and for like cause, after giving the accused an opportunity to be heard in his or her defense, the regents of the university may revoke said license.

SEC. 8. The moneys paid to the university under the provisions of this act shall be appropriated by said regents for, and shall defray all expenses incurred under the provisions of this act.

SEC. 9. The Medical Faculty shall meet on the second Monday of November, eighteen hundred and eighty-four, at the university in the city of Albany, and seven members thereof shall then and thereafter constitute a quorum, and shall at once organize by the election of a president and secretary, and such other officers as may then be determined, and then and thereafter adopt such rules and regulations, not in conflict with the provisions of this act, as may meet with the approval of the regents of the university; and shall forthwith proceed to the examination of all such applicants as shall then present themselves with the order referred to in section six of this act.

SEC. 10. Subsequent to the first day of November, in the year eighteen hundred and eighty-four, every person (except such as have before such date lawfully registered pursuant to the laws of the State in force at the time of the passage of this act), after complying with sections six and seven of this act, shall, before commencing to practice physic or surgery, register in the clerk's office in the county where he or she practices or intends to practice physic or surgery, in a book to be kept by the said clerk, his or her name, residence, and place and date of birth, together with the date of his or her diploma and by what institution granted, with date of his or her license to practice physic or surgery within this State; at the same time the person so registering shall exhibit both the license and the diploma herein required to the clerk, and subscribe and verify by oath or affirmation, before a person duly qualified to administer oaths under the laws of this State, an affidavit containing all the facts as aforesaid, and shall file said affidavit and copy of said diploma with said clerk; said county clerk to receive a fee of twenty-five cents for such registration, payable by the person so registering. Nothing in this section shall be so construed as to prohibit medical consultations in the different counties of the State between legally qualified and registered physicians of this and other States.

SEC. 11. A person who shall willfully swear falsely to any statement contained in the affidavit required by the tenth section of this act shall be deemed guilty of and subject to conviction and punishment for perjury; and a person who violates any of the other provisions of this act, or who shall practice physic or surgery in this State under cover of a diploma unlawfully issued or illegally obtained, or without a license as provided for in this act, shall be deemed guilty of a misdemeanor,

and, on conviction thereof, shall be punished by a fine of not less than two hundred and fifty dollars nor more than five hundred dollars for the first offense, and for each subsequent offense by a fine as aforesaid and by imprisonment for not less than thirty days and not more than six months. The fine when collected shall be paid, one half to the person or corporation making the complaint, the other half into the county treasury of the county where such conviction shall be had.

SEC. 12. For the purpose of this act the words "practice physic or surgery" shall mean to annex the letters "M. D." to one's name, or to suggest, recommend or prescribe, direct or employ, as a matter of business or for a fee, for the use of any person, any drug, medicine, appliance, apparatus, or other agency, whether material or not material, for the treatment, cure, relief, or palliation of any real or supposed ailment or disease of the mind or body, or for the treatment, cure, or relief of any wound, fracture, or other bodily injury or infirmity, or any deformity. But nothing herein contained shall prevent or interfere with the manufacture or sale of proprietary medicines as articles of merchandise.

SEC. 13. Nothing in this act shall apply to commissioned medical officers of the United States army or navy, or of the United States Marine-Hospital service, nor to any of the members of the house staff of any legally incorporated hospital during the term of their service as such, nor to medical students who have already matriculated in any legally incorporated medical college of this State.

SEC. 14. So much of chapter seven hundred and forty-six of the laws of eighteen hundred and seventy-two, chapter five hundred and thirteen of the laws of eighteen hundred and eighty, chapters one hundred and eighty-six and six hundred and seventy-nine of the laws of eighteen hundred and eighty-one, as are inconsistent with this act, and all other acts and parts of acts inconsistent with this act, are hereby repealed.

The College Bill.—SECTION 1. From and after the first day of June, 1884, there shall be and continue a Medical Faculty of the University of the State of New York, consisting of nine members, appointed by the Governor.

The Medical Faculty shall be, and continue to be, so constituted that every member thereof shall be a legally authorized practitioner of physic and surgery in this State, and no member thereof shall be or become connected with any medical school or college.

Of the nine members of the Medical Faculty first appointed, three shall hold office for three years, three for four years, and three for five years, from the first day of June, 1884, as shall at their first meeting be by themselves determined by lot, and certified in writing to the Governor. Except as otherwise hereinafter provided, the members thereafter appointed shall each hold office for five years from the first day of June, in the year of appointment, unless appointed to fill a vacancy occurring otherwise than by expiration of a term of office, in which event the member so appointed shall hold office only for the unexpired term.

SEC. 2. The Governor, on or before the first day of June, in the year 1884, shall appoint nine persons, qualified as aforesaid, and on or before the first day of June in every year thereafter in which terms of membership shall expire, shall appoint three persons so qualified, to be members of the Medical Faculty.

The Governor, under the conditions before prescribed, shall, by appointment for the unexpired term, fill any vacancy occurring otherwise than by expiration of term. Upon the written recommendation of three fourths* of the Medical Faculty, the Governor may remove from office any member of the faculty.

SEC. 3. From and after the first day of November, in the year 1884, no person not theretofore lawfully authorized to practice physic and surgery in this State shall enter upon or be admitted to such practice unless lawfully licensed, after examination by or under the supervision of the Medical Faculty, in the manner hereinafter provided, or unless regularly authorized by the diploma of some legally incorporated medical school or college in this State.

SEC. 4. From and after the first day of November, in the year 1884, excepting persons regularly authorized by the diploma of some legally incorporated medical college in this State, and except as provided in

* So the draft reads, evidently from a clerical error.—EDITOR.

the seventh section of this act, any person not theretofore lawfully authorized to practice physic and surgery in this State, and desiring to enter upon such practice, may, upon payment of twenty-five dollars into the treasury of the university, deliver to the Regents of the University a written application for license, together with satisfactory proof that the applicant is more than twenty-one years of age, is of good moral character, and has received a diploma conferring the degree of doctor of medicine from some legally incorporated medical college, and thereupon the Regents of the University, through such officer as may from time to time be designated for that purpose, shall issue to such applicant an order for examination by the Medical Faculty.

SEC. 5. The Medical Faculty shall hold a meeting at least twice in each year, in Albany or New York, for the purpose of examining such applicants, and at each meeting shall faithfully examine every such applicant presenting the order of the Regents of the University.

The examination shall be in and upon the several departments and branches of medical science as the same shall have been designated by the Medical Faculty, with the approval of the Regents of the University.

The questions propounded shall be such as from time to time shall have been determined and designated by the Medical Faculty, subject to review by the Regents of the University, and written answers to such questions shall be required.

Without unnecessary delay, after the close of each examination, the Medical Faculty shall transmit to the Regents of the University the answers of each applicant so examined, together with the opinion of each member participating in such examination as to the qualification and merits of each applicant, and as to his or her degree of proficiency in each of the several branches in respect of which he or she shall have been examined; which opinion shall, by the member rendering the same, be therein denominated as "favorable" or "unfavorable."

SEC. 6. The Regents of the University shall issue to every such applicant who shall have been so examined, and as to whom a "favorable" opinion shall have been delivered by seven or more members of the faculty participating in such examination, a license to practice physic and surgery in the State of New York. Such license shall be delivered only upon payment of the sum of fifteen dollars into the treasury of the university, and shall entitle the person so licensed to practice as aforesaid until such license shall have been revoked for cause as hereinafter provided.

SEC. 7. From and after the first day of November, 1884, the legally authorized medical schools and colleges in this State shall issue diplomas conferring the degree of doctor of medicine and the right to practice physic and surgery within this State after examination under the supervision of the Medical Faculty in the following manner: Whenever any such school or college shall propose to make any such examination it shall give to the Medical Faculty notice thereof in the manner which shall have been previously prescribed by the Medical Faculty, which shall, without delay, designate and appoint three of its members to attend such examination. The questions to be addressed to the candidates for degree at such examination shall be submitted to the members of the Medical Faculty attending such examination, and all answers thereto shall be open to their inspection. The expenses of such attending members of the Medical Faculty, and the compensation of each member, at the rate of twenty-five dollars per diem for each day spent in going to or from, or attending such examination, shall be paid by the medical school or college at which such examination shall be had.

SEC. 8. The Medical Faculty may, by a two-thirds vote, after having given to the person to be affected an opportunity to be heard, recommend to the Regents of the University the revocation of any license issued under the provisions of this act, or of any right to practice physic and surgery under any diploma hereafter issued, because of professional incompetency or misconduct, and unless the Regents of the University shall upon the record decide that such recommendation is not well founded, the license so issued and the right to practice under such diploma shall be withdrawn, from and after the time when such recommendation shall have been made by the Medical Faculty, and unless and until such recommendation shall have been overruled by the Regents of the University, the person accused shall not practice physic or surgery in this State, and any license issued under any former act may be similarly revoked for unprofessional or dishonorable conduct subse-

quent to the passage of this act, and after such revocation the person affected shall not practice physic or surgery within this State.

SEC. 9. The Medical Faculty may, by a three-fourths vote, recommend the Regents of the University to vacate, annul, or suspend the charter of any medical college or school within the State, and the Regents of the University, after giving to such medical college or school, through its trustees or directors and faculty, a proper opportunity to be heard, may, by a two-thirds vote, adopt such recommendation in whole or in part, and may vacate, annul, or suspend the charter of such medical school or college, or may make such determination or order as in the matter may seem proper, and thenceforth the rights and powers of such medical school or college shall exist, and be exercised only in subordination to such determination of the Regents of the University.

SEC. 10. The Medical Faculty is authorized to take testimony concerning all matters within its jurisdiction, and the presiding officer for the time being of the Medical Faculty or of any of its committees may issue subpoenas and administer oaths to witnesses.

All of the records and proceedings of the Medical Faculty shall for ever be a part of the public records of the university. Every member of the Medical Faculty shall take, subscribe, and file with the Secretary of State the oath prescribed by the twelfth article of the Constitution. Except as provided in the seventh section of this act, there shall be paid out of the treasury of the university the expenses of the office of the Medical Faculty, the actual expenses of the Members of the Faculty in the discharge of their duties, and such compensation for actual service as may be allowed by the Regents of the University.

SEC. 11. The Medical Faculty shall meet on the first Monday of November, 1884, at the University in the City of Albany, and seven members thereof shall then and thereafter constitute a quorum, and shall at once organize by the election of a president and secretary, and such other officers as may then be determined, and then and thereafter adopt such rules and regulations, not in conflict with the provisions of this act, as may meet with the approval of the Regents of the University; and shall forthwith proceed to the examination of all such applicants as shall then present themselves with the order referred to in section four of this act.

SEC. 12. Subsequently to the first day of November, in the year 1884, every person (excepting such as may have theretofore lawfully registered pursuant to the laws of the State) being licensed under sections 6 or 7 of this act shall, before commencing to practice physic or surgery, register in the Clerk's Office in the county where he or she practices or intends to practice physic or surgery, in a book to be kept by the said clerk, his or her name, residence, and place and date of birth, together with the date of his or her diploma, if any, and by what institution granted, with his or her license to practice physic or surgery within this State; at the same time the person so registering shall exhibit both the license and the diploma, if any, herein required, to the clerk, and subscribe and verify by oath or affirmation, before a person duly qualified to administer oaths under the laws of this State, an affidavit containing a plain statement of all the facts as aforesaid, including his or her age, and shall file said affidavit and copy of said diploma with said clerk; said county clerk to receive a fee of twenty-five cents for such registration, payable by the person so registering. Nothing in this section shall be so construed as to prohibit medical consultation in the different counties of the State between legally authorized and registered physicians of this and neighboring States.

SEC. 13. Any person who shall willfully swear falsely to any statement contained in the affidavit required by the eleventh section of this act shall be deemed guilty of a felony and subject to conviction and punishment for perjury, and any person who shall violate any of the other provisions of this act, or who shall practice physic or surgery in this State under cover of a diploma unlawfully issued or illegally obtained, or who, not being then lawfully authorized to practice physic and surgery in this State, shall, upon or after the first day of November, in the year 1884, practice or publicly profess to practice physic or surgery within this State without a license as provided for in this act, shall be deemed guilty of a misdemeanor, and, on conviction thereof, shall be punished by a fine of not less than two hundred and fifty dollars or more than five hundred dollars for the first offense, and for each subsequent offense by a fine as aforesaid and by imprisonment for not

less than thirty days and not more than six months. The fine when collected shall be paid, one half to the person or corporation making the complaint, the other half into the county treasury of the county where such conviction shall be had.

SEC. 14. Within the meaning and for the purposes of this act, any person may and shall be held to practice physic or surgery within this State who shall within the limits thereof suggest, recommend or prescribe, direct or employ as a matter of business or for a fee for the use of any person, any drug, medicine, appliance, apparatus, or other agency, whether material or not material, for the treatment, cure, relief, or palliation of any real or supposed ailment or disease of the mind or body, or for the treatment, cure, or relief of any wound, fracture, or other bodily injury or infirmity, or any deformity, or who shall, by prefixing to his or her name the designation "Doctor" or any abbreviation thereof, or by adding thereto the letters "M. D." or any similar designation, hold himself or herself out as a doctor of medicine or a surgeon, provided that nothing in this act shall prevent or prohibit any person, lawfully authorized by any government or incorporated medical college, from using his or her professional title for any purpose other than the solicitation or transaction of professional employment.

SEC. 15. Nothing in this act shall apply to commissioned medical officers of the United States Army or Navy, or of the United States Marine-Hospital Service, nor to any of the members of the house staff of any legally incorporated hospital during the term of their service as such, nor to any practice of dentistry, nor to any dentist in the practice of dentistry.

SEC. 16. So much of the acts, chapter seven hundred and forty-six of the laws of eighteen hundred and seventy-two, chapter five hundred and thirteen of the laws of eighteen hundred and eighty, chapter one hundred and eighty-six and chapter six hundred and seventy-nine of the laws of eighteen hundred and eighty-one, as is inconsistent with this act, and all acts and parts of acts inconsistent with this act, are hereby repealed.

SEC. 17. This act shall take effect immediately.

FETAL RHACHITIS, CRETINISM, AND STUNTED GROWTH.—Virchow, in a paper with this title, states ("Archiv. f. path. Anat. und Physiol. und f. klin. Med.") that during a prolonged residence on a certain mountain in the canton Glarus, Switzerland, where the inhabitants in general were well built and free from goitre, he frequently encountered individuals who combined with smallness of stature a species of facial and bodily malformation approaching more or less closely to the condition known as cretinism. The contrast thus produced was most strikingly displayed in the school-children of the district, especially the girls. Among these he noticed pupils fourteen or fifteen years old that were no taller than their companions of ten or eleven, from whom, however, they were readily distinguished by their squat, clumsy figures and awkward movements. Yet he never met with a case of actual cretinism in the neighborhood—not a single idiot or even remarkably weak-minded person could be found there.

In an earlier publication Virchow has shown that the form of face peculiar to cretins is the result of arrest of growth in the bones of the cranium. This occurrence he also proved to proceed in many instances from a premature synostosis of the basilar synchondroses; but it is a mistake to suppose that he sought to explain the phenomena of cretinism on the sole ground of such synostosis. On the contrary, he expressly states that this process does not take place in the case of every cretin, and also that the incompleteness of the basilar bones may be caused either by their premature union, or by a failure in the growth of the osseous structures themselves. Accordingly, Virchow ascribes the cretin-like physiognomies found among the above-mentioned mountaineers simply to arrested development—or, in other words, contraction—of the base of the skull, a condition which corresponds with their low stature and the shortness of their extremities. Individual cases of the kind are occasionally met with even among the author's countrymen, so that, in his opinion, it is very difficult to draw a precise line of demarcation between the dwarfishness of genuine cretins and that of isolated subjects who bear an external resemblance to those unfortunate. This difficulty is greatest when the abnormalities are of intra-

uterine origin, i. e., congenital. Such cases fall under the denomination of *fetal rhachitis*, a disease which can be brought into very close connection with cretinism. Curvature of the bones, however, is just as seldom met with among the people first spoken of as among real cretins. This is because, in the so-called fetal rhachitis, there takes place, not, as in cases of genuine "rickets," a free development of cartilage with delayed ossification, but rapid ossification with retarded growth of cartilage—the result of which, of course, is osseous sclerosis. At the base of the cranium this sclerosis is often accompanied by a premature ossification of the synchondroses, while, under its influence, every bone in the body is shortened.

After what Virchow has observed in other parts of the alpine region, e. g., in Salzburg and the Tyrol, he is inclined to believe, not only that a morbid process closely allied to the so-called fetal rhachitis, if not identical with it, occurs at different points throughout a wide extent of territory—sometimes associated and sometimes not with the cerebral disorders characteristic of cretinism—but that isolated cases of the same nature are met with far beyond the boundaries within which genuine cretinism is confined. He remarks that he may return to the subject at a future period; at present he merely wishes to direct the attention of other investigators to the relations spoken of.

THE INDICATIONS FOR TRACHEOTOMY IN LARYNGEAL TUBERCULOSIS.

—Dr. A. Gouguenheim ("Annales des maladies de l'oreille, du larynx, et des organes connexes," Nov., 1883), in a paper read before the Medical Congress at Rouen, summarizes his conclusions as follows:

1. Tracheotomy is an operation not often necessary in cases of laryngeal tuberculosis.
2. There are, however, certain forms of this disease in which it is imperatively required.
3. Thus, in *acute phthisis*, rapidly advancing caries of the arytenoid cartilages may give rise to fatal paroxysms of suffocation, although, in most cases, death occurs previously to this event.
4. In *chronic phthisis*, tracheotomy is called for by the following conditions:
 - (a) Caries involving the whole of the cricoid and thyroid cartilages, in which case the operation may not only save the patient at the time, but prolong his life for a considerable period.
 - (b) Tuberculous infiltration of the mucous membrane of the vestibule and superior laryngeal ligaments, forming a tumor which obstructs the cavity of the larynx. Here again tracheotomy may give the patient a new lease of life.
 - (c) Infiltration and enormous thickening of the vocal cords.
 - (d) Immobility and mutual approximation of the vocal cords, almost completely closing the glottis, with paralysis of the dilator muscles, or permanent spasm of the abductors. (In the last two cases the operation affords only temporary relief, owing to the advanced stage of the accompanying pulmonary lesions.)

FRACTURES AND POLICEMEN'S CLUBS.—The "Medical Times and Gazette" (January 26, 1884) reports the case of a woman in Dublin whose broken leg was temporarily dressed by a police sergeant who had been trained under the St. John Ambulance Society. He constructed a splint out of two batons and his duty bands, and removed her to the hospital. The "intelligence" which stands behind and directs the use of the club in the hands of a New York policeman is usually applied to breaking rather than setting bones.

THE PHYSIOLOGICAL ACTION OF COFFEE.—According to the result of experiments recently made by Messrs. Couty and Guimaraes to ascertain the precise physiological action of coffee, that beverage is not a preventer of tissue-waste. The maintenance of nutrition is, no doubt, improved by its consumption, as Gubler asserted, but simply because it involves an increased assimilation of nitrogenous food through improving the appetite, when not taken in excess, and thereby encouraging its consumer to take nutritious food.—*British Medical Journal*.

HOSPITAL CHAPLAINS IN PARIS.—The "Lancet" (January 6, 1884) states that the abolition of chaplaincies at the Paris hospitals has excited the indignation of the archbishop of the city, who advises the faithful not to send the sick to the hospitals, but to organize a system whereby they may be treated at home.

ON

NEUBER'S DEEP CANALIZATION

IN

AMPUTATION OF THE FEMALE BREAST.*

By ARPAD G. GERSTER, M. D.,

SURGEON TO THE POLYCLINIC AND TO THE GERMAN AND MT. SINAI HOSPITALS, NEW YORK.

THE essence of modern wound treatment centers in absolute rest of the wound. The efforts of progressive minds in surgery all bear the character of an unmistakable tendency toward securing such conditions in and about wounds as will suffice, without further interference, to insure primary or secondary union under the dressing applied on the operating-table.

To Neuber, of Kiel, belongs the honor of having first demonstrated the possibility and entire safety of such endeavors.

Among his several important innovations, the idea of what he calls "canalization" seems to be pregnant with a great deal of vitality. It deserves extended trial in the varying conditions which the general surgeon has to deal with.

Canalization may be termed a process by which good drainage is afforded to a wound, shallow or deep, without the use of drainage-tubes. It is divided into two kinds: shallow and deep canalization.

Shallow canalization is employed for draining extensive subcutaneous cavities situated beneath large skin-flaps, such as occur after amputation of the breast or the removal of large tumors of the back. It is accomplished by the aid of a punch devised by Neuber, of Kiel, a tool very similar to the common leather punch, and differing from it only in the shape of the hole made by it, which is not circular but elliptic, and measures two thirds of a centimetre by one centimetre in diameter. In an emergency a common leather punch will do very well, as I have found in one case by experience.

The mode of applying the punch is to cut as many holes out of the skin along the most dependent portion of the wound as will suffice to carry away easily all the secretions. If the wound be very extensive, it is well to scatter about a number of punch-holes over the entire skin-flap covering the wound. The punch makes a clean-cut orifice through the skin proper, out of which, however, small portions of subcutaneous fat are apt to protrude. These must be seized with forceps and removed with curved scissors.

The additional lesion caused by the punch is trifling, the holes granulate over readily, and, as a rule, are closed by the time the dressings are removed. Experience has taught that the drainage produced by these punch-holes is excellent.

Deep canalization is intended to afford drainage to the secretions accumulating in the recesses of a deep wound, as,

for instance, in the neck or the axilla. Here the injury is not merely subcutaneous, but intermuscular planes are opened up, and the dangers of retention and suppuration are far more grave than in shallow wounds, however extensive.

These deep-reaching wounds have formed, and in many cases will ever form, the true domain of the usefulness of the drainage-tube.

In the invention of Neuber's absorbable drainage-tubes an important step forward was made in the treatment of fresh wounds. These tubes are made of ox-bone, and, when decalcified and disinfected, behave in a wound exactly as catgut does—namely, in the course of from five to eight days they dissolve and become absorbed.

Thus the act of eliminating the drainage-tube, formerly requiring a removal of the dressings, goes on spontaneously without external interference.

Even an absorbable drainage-tube, however, is at best a necessary evil, and every safe simplification of the operating apparatus must be looked upon as true progress. Neuber's inventive head has again furnished a solution to the question: "Is drainage of deep subfascial wounds possible without the use of tubes?"

He advises, in suitable cases, to detach the skin on both sides of a deep wound so as to make it movable, then to turn it into the bottom of the cavity and fasten it there with a sufficient number of catgut sutures. In this manner the greatest portion of the cavity becomes lined with skin, and it can heal by adhesion, the funnel of cutis serving at the same time as an unobstructible channel for draining the bottom of the cavity. This is called *deep canalization*.

A and B are the detached skin flaps, the dotted lines showing their arrangement and fixation in the bottom of the cavity by sutures.

The results attained in Professor Esmarch's clinic in amputation of the female breast can hardly be surpassed. Over forty cases were treated with absorbable drainage-tubes, and healed throughout by first intention. Yet it has seemed to me that I should be justified in attempting to reach the same result in a simpler manner by utilizing Neuber's idea of deep canalization. It is an accepted fact that, together with the breast, the contents of the axillary cavity ought to be invariably removed in cancer, to diminish the possibility of relapse. This important addition to the operation is most easily accomplished by adhering to Professor Volkmann's directions. He advises to incise the skin and fascia parallel to the edge of the latissimus dorsi, then to expose this muscle, to lay the knife aside, and to proceed by blunt dissection with a pair of curved scissors until the axillary vein is exposed. Having done this, the greatest

* Read before the Medical Society of the State of New York at the annual meeting held at Albany, February 5, 6, and 7, 1884.

danger of the operation—that is, injury to this vein—can be readily avoided, and removal of the axillary fat and the inclosed lymphatic glands in one mass becomes a comparatively easy task.

The creating of so large a cavity as the preceding step will necessitate has one great drawback. If supuration be not avoided, a large mass of granulation, hence cicatricial tissue, will necessarily be produced, which, being in very close relation to the vein and brachial plexus, is apt to cause œdema of the arm, together with acute neuralgic pains radiating along the extremity. Furthermore, a massive cicatrix will mechanically impede abduction of the arm for a very long time.

Therefore it is obvious that to prevent the formation of a massive cicatrix in the axillary cavity must have many practical advantages, and that the object is worthy of the surgeon's best attention.

The use of the absorbable bone drainage-tube will accomplish all that is desired; but as yet the procuring of this commodity is well-nigh impossible to the general practitioner, and, therefore, I have thought it admissible to try Neuber's idea of deep canalization as adapted to the axillary cavity. The procedure is easy and simple, and does not necessitate the use of special instruments. The requisites besides the ordinary apparatus are a punch and some stout catgut.

The experiment did not necessitate any additional risk to the patient, and was accordingly made in three successive cases, the histories of which I have the pleasure of presenting here:

CASE I.—Miss C. H., a German store-keeper, thirty-two years old, presented a somewhat anæmic, otherwise well-nourished, exterior. For about one year she had noticed an irregular nodosity in her left breast, which had grown steadily to the size of a fist. On palpation, an irregular, movable, and not very hard swelling of the breast gland was found; the nipple was not retracted, the skin was partially adherent, the axillary glands were intumescent. Latterly, shooting pains had inaugurated a rapid increase in the size of the tumor. Amputation of the entire breast and evacuation of the contents of the axillary cavity were performed November 30, 1883. The wound was irrigated with a 1-to-1,000 solution of corrosive sublimate, and four holes were punched into the skin on both sides of the wound. The anterior portion of it was united with two continuous catgut sutures: a deep one of stout catgut to approach, and a more superficial one of thin catgut to bring about actual contact of the edges of the wound. The edges of the axillary part of the wound were dissected up for about an inch on both sides; then the anterior skin-flap was transfixed with a stout catgut suture, and, being turned well into the apex of the armpit, was sewed to the posterior aspect of the pectoralis minor muscle. The posterior flap was likewise sutured to the anterior aspect of the latissimus dorsi. In this manner the axillary cavity was transformed into a cone lined with skin, at the apex of which a small portion of the deepest part of the axilla remained uncovered. After this a strip of gauze dusted with iodoform was laid on the line of sutures, and a large pad of sublimated gauze was snugly bandaged on to the shoulder and thorax. The arm was placed in a sling. About fifteen catgut ligatures, prepared in oil of juniper, were applied to spurting vessels. The next day the patient's temperature, taken in the vagina, rose to 101° F., but fell to the normal standard on the day following, to remain

there permanently. Solid food was given, after an evacuation of the bowels, on the fourth day. The patient left the bed on the eighth day, and could not be induced not to use the arm of the affected side from the eleventh day on. A fortnight after the operation the first dressing was removed, and the entire wound was found to be healed by the first intention in the literal sense of the word. Seventeen days after the operation I found my patient selling goods to her customers, and the motions of the left arm, especially abduction, remarkably unimpeded. The tumor was found, on microscopical examination, to be an adeno-sarcoma containing a large number of miliary cysts.

CASE II.—Mrs. E. W., thirty-seven years of age, married, had had ten children, of which the youngest was six months old; had not nursed any of them, and had never had an inflamed breast. She was extremely lean and emaciated, and had missed her courses for the four months preceding. Three months before I saw her a small, very hard, round node had made its appearance in the inner lower quadrant of her left breast, and had attained the size of a large English walnut. The glands of the corresponding armpit could not be made out clearly. Except where the tumor lay, the flat, lean breast gland could be readily felt under the shriveled skin. I expected an easy operation, but, on performing it (December 17, 1883), was disappointed by meeting with an unusual amount of arterial hæmorrhage, requiring redoubled attention on account of the ill-nourished state of the patient. Forty catgut ligatures had to be applied to the breast wound proper. The axillary fascia being cut into, a number of small, infiltrated glands were felt close to the axillary vein, and were easily removed with the surrounding fat in one mass. Punch-holes, sutures, and dressings were applied exactly as in the foregoing case, the patient was brought to bed, and her collapsed condition was attended to in the usual manner. On December 18th her temperature rose to 100·5° F., and she had rallied nicely. For the first night she had received one eighth of a grain of morphia, and the following day had some difficulty in passing urine. December 19th a large number of fibrinous, cast-like masses were passed *per urethram* with much pain, and were followed by the evacuation of bloody-tinged urine. No catheterism having been practiced, the causation of this croupous cystitis remained a mystery. The thermometer recorded 101° F. on December 20th; on December 21st and from this on, 99·5° F. The bladder trouble soon subsided, especially after December 24th, when she left her bed. Two weeks after the operation the first dressing was removed, and the wound was found to be healed throughout. A few drops of pus escaped from one stitch on pressure. The cicatrix, therefore, was covered with a strip of iodoformized vaseline. Her appetite being excellent, she had recovered sufficient strength to attend to her household duties from the twentieth day on after the operation. Subsequent examination has shown that the woman was four months pregnant at the time of the operation.

In this case also the freedom of the motions of the arm on the affected side is very noticeable. The tumor was found to be a tubular form of adeno-carcinoma (Billroth's nomenclature).

CASE III.—Mrs. M. W., sixty-four years of age, of a robust physique, had had three children, whom she had nursed herself, during which time she repeatedly had sore nipples. About a year ago she sustained a bruise of the left breast, followed by a painful swelling, which had never subsided. For the past three months the breast had been growing much larger. I found a well-characterized scirrhus breast, with deep retraction of the nipple, and extensive infiltration of the axillary

glands. Removal of the entire breast and evacuation of the axilla were practiced at the German Hospital on January 5, 1884, the latter part of the operation requiring very extensive and careful dissection. The punch and sutures were applied in the above-described manner, the dressings in this case consisting of a smaller bag filled with sawdust laid on the wound, and this covered over with another larger pillow filled with "excelsior" or fine shavings, both this and the sawdust having previously been soaked in a 1-to-500 watery solution of corrosive sublimate. I here present to you these dressings, removed on the twenty-first day after the operation. The small amount of soiling by the secretions is remarkable, and will commend itself to everybody. The wound was found healed by first intention, except a small granulating patch in the bottom of the axilla. The diagnosis of scirrhus was confirmed by the microscopical examination of the tumor. This patient had a normal temperature throughout, and also sat up out of bed on the ninth day after the operation. She has attained considerable freedom of motion of the affected arm.

The limited experience gathered in the foregoing cases seems to justify the assumption that, where Neuber's bone drainage-tubes can not be procured, primary union of the entire wound made at a normal amputation of the female breast can, by the employment of deep canalization, nevertheless be attempted and accomplished under one dressing.

THE ESTABLISHMENT OF HOSPITALS IN SMALL CITIES.*

By EDWARD H. PARKER, A. M., M. D.,

POUGHKEEPSIE, N. Y.

It is now thirteen years since half a dozen gentlemen, who had met socially, were discussing the needs of Poughkeepsie, the city in which they resided, and it was agreed that the most urgent demand was for a hospital. The almshouse was the only institution to which persons accidentally injured, or taken ill suddenly, could be sent. As many who were not paupers were liable to be so afflicted, but a small portion of those needing care were thus provided for. It was therefore determined to establish a hospital. This paper is written in the hope that it may encourage others to establish similar institutions in small cities by showing them how much they can accomplish; what their probable expenses will be; how they can be managed; and how they can avoid some of the difficulties with which we had to contend.

The population of Poughkeepsie is about 20,000, and one of the first questions was, How large a hospital does such a population require? This problem was complicated by the fact that it might reasonably be expected that the neighboring portions of Dutchess and Ulster Counties would furnish patients needing the care of such an institution. Besides this, we had no basis on which to estimate the probable demands which would be made by accidents occurring on the railroads in the county and on the Hudson River. Our conclusion was that we could not tell how much room would be needed. However, having determined to

make a beginning, a small frame house was rented, in which seven patients could be received. A charter, under the general act for the incorporation of charitable institutions, was obtained in March, 1871, with the title of St. Barnabas Hospital, and we were ready to receive patients on the 17th of May in the same year. Since that time the hospital has been carried on continuously, thus completing more than twelve years of service. In 1873 a brick building was bought for \$5,200, and the patients were transferred to it in October of the same year. Inasmuch as the purchase was made complete, no mortgage or other incumbrance existing upon it, we have since been saved the item of rent, although necessary repairs and, for a time, taxes have had to be met by the corporation. This course should always be pursued when it is practicable, for otherwise the caprices or necessities of landlords will make the very existence of the institution uncertain, while a mortgage seems to vexationously the funds contributed for the benefit of patients.

One thing surprised us somewhat at this time. As soon as it was known that the trustees of the hospital were looking at premises with the idea of purchasing them for that institution, the whole neighborhood was stirred up to prevent the purchase. The idea seemed to be that a hospital must be a very undesirable neighbor; why, I never could learn, unless it was that a constant procession of mangled persons to the building and as constant a succession of funerals from it were anticipated. The negotiations for the purchase of the building had to be kept almost secret, and, if they had been known, we have reason to believe attempts would have been made to prevent the completion of the bargain. For more than ten years we have occupied these premises, and all opposition to the hospital has disappeared. I am not certain, however, that the same difficulty would not again arise if it were necessary for us to change its location. In the building now occupied as the hospital the number of patients easily accommodated is thirteen, but, if it were necessary, we could put up six more beds by utilizing rooms which are ordinarily appropriated to other uses. We have never been obliged to put up more than two extra beds. It is also our general rule to keep one bed vacant, so that we may be able to receive any one who has been accidentally injured. Such persons are received into the hospital immediately on being brought to it. It is expected that in all other cases application for admission shall be made to the matron of the institution, and, if there is a vacancy, the applicant is visited by the physician or surgeon on duty, who decides whether or not the case is a proper one for admission. If his decision is favorable, one of the trustees signs the permit for admission, it resting with him to determine whether or not any payment is to be made for the patient, and, if so, how much. This routine is sometimes inconvenient and is departed from, but the wisdom of the general rule is very apparent. As before said, injured persons can be brought to the hospital immediately without a permit; for all other applicants there is abundant time for the above-described routine, and it is necessary to protect the institution, which might otherwise be filled with patients for whom it was not intended. As is the case with other charitable institutions, the attempt is sometimes made to saddle

* Read before the Medical Society of the State of New York at its seventy-eighth annual meeting, held at Albany, February 5, 6, and 7, 1884.

us with undesirable persons, or to find comfortable quarters for others for a season. It is in winter that we have to be especially on the lookout for the latter class. The hospital is intended to be for the benefit of persons suffering from acute non-contagious diseases, or requiring surgical treatment. Still the rule against others is not an iron one, and we almost always have one or more cases which would properly be excluded by it. Sometimes, when crowded by cases of acute disease, or by accidents, it has been necessary to insist that chronic cases should be removed by their friends. Occasionally this seems rather hard, but full explanations soon satisfy all parties of its necessity.

The corporate powers of the hospital are vested in nine trustees, who have the power of filling vacancies, with the exception that the rectors of the three Episcopal churches are *ex-officio* members of the board. Two laymen are elected from each parish. The easy working of so small an institution requires a small board of trustees, increase in their number increasing the chances of disagreements and divisions.

A board of lady managers, fifteen in number, appointed by the trustees, look after the general condition of the various supplies, see that the rooms are neatly kept, and, from funds raised by themselves from their own donations and fines for non-attendance at their meetings, supplement little luxuries and conveniences which, although they may not be absolutely necessary, add very much to the comfort of the patients. A matron superintends the hospital, selects her own servants, and with them does the nursing. A male nurse, who is expected to make himself generally useful, is constantly employed.

The medical staff consists of four physicians and four surgeons, who are appointed by the trustees, though, when vacancies have occurred, the nominations to fill them have been made by the staff. This seems to be the wisest course, to avoid the introduction of discordant elements. It may be worth while to say that there has never been any jar among the medical men, but always the most complete harmony. No medical officer is resident at the hospital. Visits are made by the physicians and surgeons regularly, and, in cases of emergency, at any time of day or night, as may be necessary. The surgeons have sometimes had occasion to pass a good share of the night at the hospital, but the most exacting demands have been as promptly met as in private practice. The surgeon on duty operates, or directs the treatment of the patient after consultation, if necessary, as to the course to be pursued. In case of emergency or of the detention of the surgeon on duty, either member of the staff, as may be most convenient, acts for him.

The term of service is two months only, in order that the season of the year in which each serves may be gradually rotated. Three months' service would always give to one the hottest and to another the coldest part of the year. One physician or one surgeon goes out at the end of each month.

No resident pharmacist is employed, nor are any drugs kept on hand at the hospital, excepting anesthetics and such medicines as would ordinarily be required in so large a family—say quinine, castor-oil, Dover's powder, etc. These

are dispensed by the matron on the direction of the medical attendant. Prescriptions are written for each patient exactly as they would be in private practice, and a duplicate is kept at the hospital. Arrangements are made with a druggist to put up these prescriptions at a wholesale price. The advantages obtained by this method are, first, that of economy, and, second, that we avoid the temptation to substitute something which is on hand for what is really needed. How economical this method is can be judged from the fact that our bills for drugs (excluding alcoholic stimulants) for the last year amounted to only \$118 for seventy patients treated for 2,290 days. This was only eight dollars more than we paid for milk during the same time. And yet no necessary expense for medicines is spared.

In this connection it may be worth while to say that for a year the experiment of opening a dispensary in a more central part of the city was thoroughly tried. It was found that the persons who really needed such help were not in sufficient numbers to justify us in incurring so great an additional expense and adding so much to the task of the physicians. As usual, there was a constant attempt to obtain free advice and medicines by those who could afford to pay for both.

The number of patients treated in twelve years is 734. During the last year 70 were treated, and the whole number of days in the hospital was 2,290 for the year, an average of a little less than 33 days for each patient. The construction of the water and sewer systems of the city during this time has given us more than the average number of accidental injuries to treat, while two years ago the building of the West Shore Railroad threatened at one time to swamp us. As is the case with all hospitals receiving surgical accidents, patients are not infrequently brought in when almost moribund, swelling the percentage of deaths. In the twelve years the number of deaths in the hospital was 77; the number discharged recovered is 510; of improved, 103.

The diseases and operations have presented the ordinary varieties, which it is not worth while here to recapitulate. Two ovariectomies, one double and one single, have been done by the surgeons of the hospital, both patients making good recoveries.

As to the important matter of expense, I should say that, inasmuch as all our income is from donations, it has been the constant effort of the trustees to be as economical as possible, consistently with the best interests of the patients. No diet-table is arranged, and I do not think any is necessary in so small an institution. No general table is kept. We tried it, and it did not work well. Each patient has a portion sent to him in the ward, convalescents as well as those who are very ill. The diet of each can thus be varied as may be necessary, and the possibility of regulating the quantity prevents a surfeit. While no especial diet is arranged for a particular day of the week, the matron takes good care to furnish a desirable variety. The fact that when the hospital is full the whole number of patients is not greater than the number in a single ward of large hospitals makes this course entirely practicable—provided that the matron understands how to do it. Complaints of the

diet are rarely made by the patients. To make an estimate of the cost of these small hospitals, I have compared with the last report of St. Barnabas Hospital the last report of the Board of Managers of the Auburn City Hospital and the last report of the Board of Trustees of the Highland Hospital in the town of Fishkill, in Dutchess County. During the year covered by these reports, the Highland Hospital treated 28 patients at a cost of \$1,118, the Auburn City Hospital treated 60 patients at a cost of \$2,185, and St. Barnabas Hospital treated 70 patients at a cost of \$2,182. The expense *per capita* was, for the Highland Hospital, \$39.50; for Auburn, \$36.25; and for St. Barnabas, \$31.10. The first is a little higher than the average expense at the Highland Hospital, the two preceding years giving, respectively, \$36 and \$37, while the figures for our hospital are a little lower than they have sometimes been. My opinion is that it is fair to say that the average cost for each patient is \$35 a year. The number of beds in the other institutions is not given in the reports, but 13 beds in our hospital, costing last year \$2,182, give an average of \$168 a bed; or, if we call it 12 beds, the average is almost \$182. I think it is a fair estimate that for such institutions each bed will cost about \$200.

I have said that the income of our hospital is from donations. For a few years past the Board of Supervisors of the county have given the hospital from \$300 to \$500 a year, which may be reckoned either as a donation, or as payment for services rendered. Besides this, a small amount is paid by some of the patients, or their friends for them. Six dollars a week is the highest charge made, but if they can pay only one dollar a week it is taken. Not only does the hospital need the money, but it is better in every way that the patient and his friends should not feel that they are soliciting charity like paupers, if it can be avoided. These sums are, of course, reckoned in our income. The surgeons use their own instruments and appliances in treating the hospital patients, which, of course, lessens the expenses to the institution. In fact, when special instruments are needed which we do not happen to have, we buy them ourselves.

It may have been observed that the trustees of the hospital are of one religious body. They are Episcopalians. Without a word of explanation, it might be thought that the institution is used for proselyting, which is not at all the case. Evening prayer is read at the hospital every Sunday afternoon by a clergyman or lay-reader. The patients are entirely at liberty to attend or not, as they prefer. But it was from the first determined that all the patients, especially those who were approaching their end, should be placed under the care of ministers of their own religious preference. The trustees were not certain that this could be done if a variety of beliefs were represented in the board. We knew that we could do it. Accordingly, we give perfect control in religious matters for each patient to some minister of his belief. The Roman Catholic priest has as complete access to his parishioner as he could have in a hospital under the control of the Sisters of Charity. So it is with all the Protestant denominations, and so it would be with the rabbi if we had an Israelite in the hospital. We have thus avoided difficulties which have been serious in some

hospitals, and are at the same time spared the pain of seeing people die with as little spiritual direction as if they were cattle. The result has been to disarm all hostile criticism, and the hospital is to-day our most popular charity. Roman Catholics and Protestants of all shades alike contribute cheerfully to its support.

Hospitalism we do not have. The great abundance of pure, fresh air permits us to place more beds in our little wards than would be justified by the estimate for needed air-space made for large hospitals in crowded neighborhoods.

Does such a hospital pay for the trouble of carrying it on? I say yes, decidedly. It is something to have been of use to more than seven hundred persons in twelve years, and to be certain that most of them have been restored to health and usefulness by our care of them. I confess that I have been disappointed at the small amount of pathological and other strictly scientific study obtained from the hospital. It does not at all compare in this respect in its proportion to that of large hospitals, but I hope that we shall hereafter be able to do better.

Is this small number of beds sufficient for the demands of a city of the size of Poughkeepsie? Again I say yes, when limited to surgical and acute non-contagious diseases. A larger hospital could be filled, and it is probable that a larger one will at some time be built in our city. But this supplies the needs of our city and its neighborhood. The knowledge of this fact will, I trust, remove a common opinion that, even in small cities, a much greater provision must be made if a hospital is to be established—an opinion which too often hinders those who would otherwise undertake to found them.

THE THERAPEUTICS OF THE FUTURE.*

By SAMUEL S. WALLIAN, A. M., M. D.,

BLOOMINGDALE, N. Y.

THE "art divine of killing pain and patients"—so mercilessly satirized by Byron and so universally traduced by some scientific and many pseudo-scientific writers of all ages, even by some of its own accomplished and brilliant votaries, as witness Harvard's medico-literary eccentricity, the "Autocrat of the Breakfast Table"—is yet far from compelling recognition as a science. This, however reluctantly, we must all frankly admit. It may be a humiliating confession, especially to the younger and more enthusiastic in the profession, who have allowed themselves to dwell on exaggerated pictures of assumed "medical progress"; but our best and most accomplished representatives are still painfully toiling, if not actually in the dark, yet in a kind of scientific twilight. In crowded hospital wards and dingy chemical laboratories they are patiently and perseveringly observing and recording one-sided facts, half-facts, and glimpses of glimmerings of facts; slowly accumulating data on which to build theories and out of which to evolve hypotheses; striving to arrange incoherent fragments, and to harmonize incongruous and inexplicable phenomena; skim-

* Read by title before the Medical Association of Northern New York, at Malone, October 2, 1883.

ming bubbles from a fountain whose purest waters are evidently unfathomable depths below.

Still are we balked by the phenomena of a simple fever; in doubt whether typhoid, diphtheria, cholera, tuberculosis are contagious, infectious, epidemic, hereditary, zymotic, or what not; unsettled as to the nature of eczema; is it simply an acute or chronic local or general dermatitis? is it a constitutional taint allied to lithiasis or rheumatism, or does it really hinge on the neuroses?

How diffidently and how differently we discourse of yellow fever, of the nature of miasms, the laws of contagium! And how stupidly helpless are we, as yet, in the face of anthrax and angina pectoris, of Bright's disease and carcinoma, diabetes and diphtheria, exophthalmic goitre, hydrophobia, and malignant pustule!

Thus the list of vital topics—frightfully vital because frightfully fatal—of which we know next to nothing, might be extended through the entire alphabet.

Painfully and almost timidly we plod on, studying, as best we can with the meager and unsatisfactory light and facilities yet available, the minute and multiple phenomena of a something, or the absence of something, we call *disease*; noting and analyzing its thermometry; charting its sphymology; classifying and limiting its stages and periods; estimating its precursory and prevailing signs; locating its anatomical lesions and forecasting its prognosis; speculating with astute and labored display of subtle analysis and ingenious hypothesis—another name for scientific guessing—yet in the end virtually and more or less meekly admitting that we can scarcely do more when we do our best, or our worst, than to modify and, in some instances, slightly abridge its fixed and invariable course! What un-failing refuges from our admitted ignorance are expectancy and self-limitation! It is only our younger, less-experienced and over-sanguine members who feel such zealous and unhesitant confidence in their own skill and in the definite and mathematically estimable potency of remedies.

Taking a little liberty with the poet:

“ . . . oh, how sore
The fond romance of *twenty-two*
Is parodied ere *fifty-four*!”

Humiliating confessions, to be sure, but confession is urged as a moral prolylactic, and we who live, move, and have our being by listening to the confessions—and respirations—of others should not hesitate, occasionally, to be honest with ourselves and science by seeking the confessional.

We have our medical and surgical hobbies and our periodical crazes. Fashions come and go as with milliners and haberdashers. Mercury, the bromides, chloral hydrate, carbo-lic and salicylic acids, alcohol, quinine, iron, electricity, Listerism, and scores of others, have all had a more or less brilliant “season.” Most of them have now been superseded or assigned to secondary rank in the changing repertoires.

The craze of the day is the somewhat hypothetical *germ*. And still the experimenters quarrel among themselves and are asking, “Is it, or is it not?” and “Whom shall we crown king, Koch or Spina?” “Shall we label these demonstrated

forms *rod-bacteria*, or only *fat crystals* and coagulated fibrin?” “Is the *Bacillus tuberculosis* king of the walk, and destined ere long to exterminate the race?” Do we for ever walk with our heads in a cloud of poisonous flies, our lungs permeated, at every inspiration, with deadly microspores; and is the wretched meat and drink by which we manage to eke out a brief, parasite-pestered existence, thick-planted with ova and embryotic germs, only waiting for a nidus in which to develop, to revel, multiply, and destroy?

Or is the profession suffering from epidemic and contagious microphobia, a possible, progressive, antero-posterior, multilocular, and disseminated sclerosis of the bulbus rha-chidicus?

Under the inexorable law that the fittest survive, shall bacteria be enthroned the multifold but real Rex Magnus, whose fiat none can evade or effectually oppose? Then we are outgenerated and actually outlived, even while yet alive, by the latest-discovered and lowest-organized forms of animal (?) life.

Rather, shall we not be, eventually and in good time, compelled to assume and admit that the vital principle, as manifested in the higher organized forms, is under all circumstances and for ever a law unto itself; that, by no possible edict or accident in nature, on the earth beneath or in the heavens above, can a lower supplant and supersede a higher organization; and that polyonomous and polymorphic bacteria are but primary links in the endless chain of vital metamorphosis, the carrion birds that ever shadow the carcass even long before *rigor mortis* has asserted its rugged and mysterious presence; inert germs which—omnipresent—can not warm to life or have their miserable being except as a natural and inevitable part of the processes of degeneration, decay, and disintegration?

Are we “scientifically” but blindly wasting time, money, material, and all too valuable lives in the minute elucidation of non-essentials—the modes of germ-propagation, the form and size of micro-organisms, the nature of plastide, the scarcely distinguishable tints of spectroscopy? Frantic to extend the already next to interminable list of “remedies,” how few of us pause to realize that we do not yet pretend to know by what law any material element can be made to act the part of a direct and absolute “remedy”!

Perhaps the ancients were nearer to truth because they were nearer to nature. *Earth, air, fire, and water*. We have no more than these, turn where we will. To fill the pages of our ponderous dispensatories we have ransacked earth, air, and water; breezy forest, blooming meadow, and dank morass; teeming valley and arid desert, mountain heights, and deepest mines; yet the whole voluminous repertory is but a series of reiterations of that very limited round of chemic elements whose symbols are all expressed by half a dozen letters of the alphabet.

Given the two or three thousand, more or less, “remedies” of the books, a crucible and white heat, what remains? Something is vaporized—air and water; some ashes are left—these are earth. This much we know through our crude and bungling system of analysis; of their occult law of synthesis—origin, growth, reproduction—we

know absolutely nothing. Elated with the seeming results of our physiologic experiments, we say, in a confident sort of way, that our "remedies" have various *actions*, as physiologic action, pathologic action, toxic action; whereas we ought to know, and it is charitable to assume that we really do know, that the term is a palpable misnomer, a mere linguistic habit which nobody stops to question, simply because it has so long been chronic—has such venerable and ancient authorities among its ancestry.

This may be our very primary block of stumbling—the original and unpardonable sin of science. Given a false premise, all deductions are awry. It makes a wide difference whether the mountain came to Mahomet, or Mahomet went to the mountain. Parrot-like we go on repeating the thoughtless and impossible fables: "*The sun rises*," "*the moon wanes*," "*planets and the earth revolve*"—"remedies *act*!"

Reverting to first principles, *the vital forces do all the acting*. All passive materials—food, drugs, "remedies"—succumb to this; are inevitably and invariably in the *objective*; can never, by any possibility, assume the *subjective*. Barring the fixed and law-limited "action" of the mechanical forces, and the definite but only half-understood laws of chemical affinity, this assertion becomes a truism. When we attempt to reason otherwise, with however formidable array of erudition and corroboratory experimentation, we are sopping our intellects with sophistry.

This presumed and assumed "action of remedies" is the most ancient and universally honored, and at the same time most fatal to scientific progress, of all our chronic delusions. Does croton-oil or cantharides actually blister? If so, let us "blister" the cuticle of the cadaver! But for the set phrases of the books, to which we have so long given passive assent that we have come to consider them established facts, *a priori*, it would be evident enough that the raised epidermis and the exuded serum are the defenses thrown up against an intruder—the *expressed resistance of the vital forces*. Nothing more, nothing less. How does Epsom "act"? It is simply expelled *via* the alimentary canal, well diluted with gastric and intestinal secretions, and with whatever excretions and accumulations may be encountered *en route* to render it less obnoxious, nature weeping slimy tears in very humiliation and disgust at contact with the nauseous "remedy"! Unorganized matter can not possess volition; it is inherently passive and inert. The tides do not "rise"; they are pulled up by the moon. Waves do not "dash"; they are themselves dashed by the wind; and the wind in turn is but a passive plaything obeying the simple laws of barometry—gravitation.

But for the universal currency of the counter-fable it would seem to be inexcusably pedantic to cite so palpable an altruism; yet, doubtless, it will require another century of practical blundering, because of starting from a false premise, to thoroughly teach us this simple fact—a fact so simple, rational, and natural that any non-prejudiced thinker can teach it to himself with half an hour's untrammelled reasoning.

If there be one law of nature more fundamental and all-pervading than another, it is that *unorganized matter is the*

passive material with which and out of which vital force, acting through organized forms, accomplishes its results and builds its monuments. It grasps it, manipulates, rearranges, and recombines it, redistributes and rejects, but is *never subject to it*.

When we shall have practically and fully realized the force of this fundamental and inevitable law, this fact which underlies all material facts, as it applies to the study of medical science, then will the word medicine cease to stand as a synonym for mystery, and there will be no more prizes offered by learned bodies for the best essays on the "action of remedies."

Not that there will no more mystery, for the very nature of this same vital force is, as yet, and mayhap always will be, the profoundest mystery. Well may we stand aghast at the awful revenges wreaked by it—say in the contagium of variola, yellow fever, cholera; the loathsome ulcer of syphilis, the deadly virus of rabies; at the parting sigh it utters through the subtle ptomaines of the dead-house! These and a hundred other chemico-physiologic phenomena remain to belittle our pretensions and cure us of self-conceit.

In the coming medical practice it must needs be that *therapeutics* will have been largely superseded and always preceded by *prophylaxis*; and the therapeutic teachings of the future will doubtless more fully recognize that law which is ever aiding all our remedial endeavors—the *vis medicatrix nature*—without which our art would be poverty-stricken indeed. Abandoning superstition, whose wraith in one form or another still haunts us, our philosophy must revert more practically and more literally to the four elements, *earth, air, fire, and water*, and their direct derivatives, in their pristine simplicity.

The earth shall give us not merely its hoard of crude minerals, but their sublimated energies, subtle magnetisms, the *Od* force of the mystics; "high potencies" in every sense but that of the originator of the term. Not crude galvanic shocks evoked by acid corrosion of zinc and copper, gold and silver, but vitalized and dynamized currents so subjugated, tempered, and refined that they will blend with and supplement the living forces, vital currents, which energize and perpetuate every organized being. Nor will it be, as now, a matter of indifference what elements are used or what exciting media. Every material element, metal and metalloid, will have its specific and individual influence—magnetism (?)—province, so accurately analyzed and understood that each will have its demonstrated range of applicability, and there will no longer be taught the present inaccurate indifference as to whether the exciting and transmitting solution be potash or copper, ammonium or silver; or whether the current be constant or induced, primary or secondary, stable, labile, or static. Every element, whether solid, fluid, or gaseous, will have its particular, recognized, and clearly defined sphere, and will not be, as now too often, invoked to do duty alike in neuralgia and narcotism, paralysis and asphyxia, innervation and electrolysis.

To keep abreast with advances in other sciences we must have a practical and reliable *electro-pathoscope*, which, by a well-defined system of detected and recorded reflexes and

responses, the presence or absence of irritabilities—sensibilities, resistances—will render positive information, accurately and in minutest detail, as to the condition and needs of every remotest organ, structure, and viscus of the living body.

Thus shall we be enabled to substitute *actual knowledge* for the, at best, only probable and approximate intelligence we now glean through the stethoscope, the sphygmograph, the aspirator, and the microscope. Even the mysterious vital force itself will, perhaps, with all its manifold resistances and reactions, come to be accurately estimated in *volts* and *ohms* with as much facility as we now measure the power of a galvanic battery, a voltaic pile, or an induction coil. Nor is this chimerical when we appreciate what has been realized in the telephone and phonograph.

Again, the *air* must be made to give us, more perfectly than now, the breath of life. It must be amply supplied in its virgin purity to every human being, young and old, rich and poor; no longer robbed of its vital element nor loaded with noxious gases, floating germs, and impalpable emanations.

What can we do without and what can we not do with the elements of common air. We must have oxygen with every breath and drink it with every draught, move in it at every step. No potable liquid exists without oxygen as its essential element, and not for a moment can the blood be sustained without intimate contact with it. In short, as a physiologic agent it is essential and indispensable at every step of every vital process; nor is it less important or less omnipresent in therapeutics. Select important drugs from what source we will, are they not chiefly good or bad about in proportion as they combine or yield free oxygen? *Vide* the carbonates, chlorides, nitrates, and sulphates; is not their primary condition essentially that of an oxide, and are they all comparatively valueless until decomposed in the presence of the vital organism?

This is a field of inquiry which will bear extensive exploration at the hands of our physico-chemical investigators, and would doubtless yield more interesting and practical results than all the labored and endless analyses, isolations, and comparisons of alkaloids, glucosides, and proximate principles.

The ancients recognized but three ordeals of purification—*air*, *fire*, and *water*. Hence for criminals they erected the gibbet and exposed their bodies indefinitely to the winds of heaven, or they resorted to pyre and fagot, while their therapeutic reliance and universal means of physical purification was the bath. In each of these the potent factor is oxygen. Without it there could be neither air, nor fire, nor water. The first food of the infant at birth and the last gasped for by the departing patriarch is oxygen. We may abstain from ordinary and grosser means of physical sustenance for days and weeks with impunity; robbed of oxygen, we do not survive so many minutes. Tanner prolonged his fast from meat and bread, even to the period of the original deluge, without serious discomfort, but he constantly required and really subsisted on air and water—oxygen.

Thus this element presides alike over life and death, primary origin and ultimate destruction; at once a boon

and a bane, inestimable friend and relentless destroyer. Every vital process—construction, maintenance, repair, disintegration—is accomplished directly or indirectly through the agency of oxygen. Priestley would have been justified in naming it *zoogen*, since without it animal existence would have been an impossibility. Even the rocks and minerals of the earth's crust have no natural existence except in combination with it, some of them yet refusing to be dissociated from it, but requiring to be studied through their oxides. It is in every drop of blood that circulates, in the gastric fluids that digest, in the mucus that lubricates, in the very tears we weep. Remove it from water, and there would be no fountains, no flowing streams, no sounding seas, no fluids of any kind. Rob the air of it, the populous earth would become only a vast sepulchre, and the beds of the oceans would be transformed into fathomless abysses filled with irrespirable gases.

Dismissing these fairly startling but really superfluous speculations, it is high time we had practically realized, for we already theoretically admit, that this all-pervading and commonplace element can not be replaced, scarcely supplemented; that there is no known disinfectant or eliminator comparable with it; that disease-propagating germs can not withstand a free supply of it, but are soon robbed of their virulence or destroyed in its presence. The bacteria, vibrations, microspores—even the dreaded bacilli of tubercle (?)—shrink from contact with it and are rapidly robbed of their virulence—oxidized out of existence.*

The normal and only unobjectionable and universally efficient antiseptic is pure oxygen. With all our vision-straining and laboratory research, our ephemeral fashions of carbolic, boric, benzoic, and thymic acids—the latest mania being for bichloride of mercury, most dangerous of all, the very Moloch of our materia medica—to this must we come at last!

The future study of the much-vexed and much-agitated question of ventilation must resolve itself into an inquiry as to the best and most economical means for naturally procuring or artificially supplying more oxygen.

How easy to for ever banish from our crowded city institutions the dreaded ghoul of surgical erysipelas, septicæmia and hospital gangrene! The day will come, too, when the deadly upas which now flourishes in the basement, under the misleading name of "hot-air furnace," will be robbed of its baneful influence and effectually counteracted by an oxygen retort.

In *fire* is broached the whole comprehensive subject of temperature, including climatology, cookery, the warming of dwellings, public buildings, dispensaries, and hospitals, as well as the but half-understood thermometry of health and disease.

Who shall say it is wholly utopian to predict that one day we shall possess ourselves of convenient and accurate self-registering apparatus by which the general systemic, and also the local, regional, and internal temperatures of the diseased body will be carefully detected and periodically re-

* *Vide* Pasteur's conclusive experiments in chicken-cholera; and those of our own Professor Law in the cattle-plague and hog-cholera of this country. "Med. Record," June, 1881.

corded, so that the medical adviser need not thereafter be dependent on the careless manipulations and inaccurate reports of indifferent or incompetent attendants, nor limited to one or two observations per diem? Surely this ought to be possible in the not too far off future.

The subject of heat involves so much that is intimately associated with every vital process that it is very comprehensive, including the regulation of the warmth of the body, the form, size, situation, and plan of construction of dwellings, the kinds and use of fuels, the composition and make-up of fabrics used in wearing apparel, and thus the very fashion of the garments we wear.

Heat induces and hastens oxidation, and oxidation is the flexible synonym for fire. A certain range of temperature is a prerequisite in all physiologic, and one of the leading factors in most acute pathologic processes; and, after all, what is pathology, essentially, exactly, more or less, than disturbed or morbid physiology?

If it thus readily and naturally appears that *earth* means much more than the exhibition of a few mud-baths, as practiced by some eccentric Germans, or than the adoption of antiseptic dressings of desiccated and pulverized mold or clay for foul, phagedenic or sloughing wounds, as advocated by some very reputable American surgeons; or the aggregation of innumerable salts, the carbonates, chlorides, oxides, sulphides, lime, soda, potash and phosphorus, lead, mercury, silver, and zinc; the use of *air* signifies much more than the question of bare respiration; and that the word *fire* imports much that is not demonstrated in the lighting of a bundle of fagots—so the subject of *water* comprehends much that is not included in works on navigation.

Concerning the value of quinine and its congeners as antipyretics, the discussion still has two sides; but there is very little dispute as to the antipyretic potency of water; while not a few of our best practitioners, if compelled to choose between a bottle of quinine and a barrel of water to control a fever, would make no hesitant decision in favor of the latter!

Water joins with air in supplying us the elements of our daily bread. In earth, air, and water we find all needed material for organization, growth, and repair. In water we have the only universal solvent and vehicle. It is the one faultless medium of transmission, whether of heat, force, or electricity. It washes away our physical sins, directly or indirectly drives the major part of the vital as well as mechanical machinery of the world, and is equally essential with air in the genesis and maintenance of all vegetable and animal life. Nine tenths of every animal body is water. Deprive the tissues of their constituent water, they become parchment; wholly desiccated, they crumble to impalpable dust. These are homely facts—more would be glaringly superfluous—familiar to every tyro in physics, yet their import has all along, for ages, as it were, fallen on practically unheeding ears. Now and then, it is true, a Barker, a Bartholow, a Flint, or a Thomas recognizes the efficacy of cold sponging, the warm bath, or the hot douche. Hot water is coming to the front as the one efficient, universally applicable and universally safe hæmostatic. Formerly the ether spray or ice to the hypogastrium, or styptic injections,

for metrorrhagia; now the continuous, hot vaginal douche. Once, irritant mustard and the fly-blister, now the spongopilin, hot compress, or bran poultice, for acute inflammations. Formerly tonics, absorbents, and astringents for gastric catarrh; now free, regular, and systematic hot water drinking at stated intervals—virtually, the hot bath applied inside.

How very simple, neither “scientific nor mysterious, but utterly and undignifiedly natural”! Yet if the great army of malingersers, who yearly suffer real and imaginary horrors, whether from dyspepsia, hepatic engorgement, renal disorder, or tuberculosis, could be persuaded to adopt the regimen for a month, the results would astonish, perhaps convert, both patient and medical attendant.

R Aqua fervente, Oss. ad Oj.

Succi limonis vel tamarindorum, q. s.

Vel sodii bicarbonat., grs. x, p. r. n.

S. To be sipped slowly an hour and a half before each meal and at bedtime, daily, as hot as can be borne (140° to 160° F.), and to be continued for four or six months, the quantity to be increased or diminished as required to maintain a uniform, normal, or sub-normal specific gravity of the urine.

Evidently here is something more than a mere drink of hot water. Rationally analyzed, what can be expected from it?

1. Cleanses thoroughly the primæ viæ.
2. Increases downward peristalsis.
3. Dilutes and washes away all morbid, tenacious, andropy secretions, mucus, bile, pancreatic, duodenal, and intestinal secretions.
4. Relieves visceral congestions and spasm through the relaxing influence of *heat* and *moisture* applied *inside* the alimentary canal.
5. Promotes natural elimination through all the emunctories, renal, respiratory, cutaneous, and intestinal.
6. Removes from the disordered stomach and system the acid products of mal-assimilation and fermentation—acetic, butyric, hydrosulphuric, lactic, and saccharic acids, sulphides of ammonium, vegetations, and yeast.

Years ago, in the Pennsylvania Hospital, Da Costa “washed out” the stomachs of his worst dyspeptics, using a siphon and warm water, with flattering results; but this newer practice goes much farther, washing out (almost “boiling, sudsing, and rinsing”) every vascular organ in the whole body, cleansing the system, directly from os to anus, and indirectly from occiput to os calcis.

Add to the foregoing a rational system of repair, through a thoroughly nutritious and readily assimilable dietary, and, in chronic maladies, what results are impossible?

Let us prate no more about “alteratives” and “blood-purifiers.” Here is this simple water sprite which puts them all to shame.

Says a prominent professor in one of our foremost medical universities: “There is in every science a mythological part, which is handed down from generation to generation, whose disbelievers formerly were crucified, now are ostracized. Shall I tell you where the mythology of medicine is stored up? In the hand-books of *materia medica*, *allopathic*

as well as homœopathic. But do not think me a nihilist. If I believe that nine tenths of what is said of the virtue of drugs is myth, I am convinced that the last tenth is a blessing to mankind."

Realizing the truth of this admission and availing himself, to the fullest capacity, of all natural agencies, the coming therapist will be able to move medical mountains. Unawed by tradition, and thoroughly conscious that simplest truth is truest science, his profoundest study will be to determine the simplest processes by which to unload the clogged viscous, replenish wasted tissues and fluids, relieve overtasked organs, accelerate flagging efforts, moderate overactivity whenever present, and, in short, to do naturally and without jar all that can be done to keep this mysterious vital machinery free from unnecessary frictions, wastes, and injuries, until it shall have spent its allotted modicum of energy, untrammelled and unimpeded, and at last runs down like a once-wound timepiece which has no key!

Well, the world has moved, the world does move, and even the medical world must move, whether we will or no; and, while too many would-be reformers and enthusiasts unreasoningly rush into the ranks of the therapeutic nihilists and make of themselves mere iconoclasts, smashing right and left, with no purpose but to raise an ephemeral din, there certainly is a waiting field for an earnest and conscientious corps of sham-oclasts. And so, quoting the prophetic remark of an eminent and sensible English citizen, after witnessing the puerile pageantry of the last parliament-opening by the beloved but fussy old queen: "*I'm thinking what a jolly mess we shall make of all this (therapeutic) rubbish one of these days!*"

A NEW OBSTETRIC FORCEPS.

By WILLIAM D. SCHUYLER, M. D.

THE accompanying cut represents a newly devised obstetric forceps recently made at my suggestion by Messrs. George Tiemann & Co., of this city.

Its modeling, in part new, embodies points which I deem of practical advantage over those of any other long forceps. It comprises closely approximated shanks throughout their entire length; an upward sweep of the shanks close to their commencement, which curve I term perineal; a shortened cephalic curve for the blades on their anterior extremities; a well-marked pelvic curve; narrow blades antero-posteriorly, and shortened handles, which are bent upward.

The utility of having these curves more prominent than usual, or new, will be readily appreciated by considering the indications for which they were constructed.

The first general qualification of a forceps is that it shall be adequate to deliver with—namely, that the blades shall be properly formed to grasp the head and retain their hold, and that the instrument shall be sufficiently strong throughout to stand the required degree of traction to be exerted through it.

The second general qualification is that the forceps shall be so modeled that it will not act with unnecessary harshness upon or do injury to the mother's parts.

As all, or nearly all, forceps prove their competency as instruments of traction simply, the problem offered by the

first general requirement has for that reason not been difficult to solve. In view, however, of the many serious and frequent injuries which attend the use of these instruments, it evidently has not been a simple task to successfully meet the second requirement.

Considering the great practical value of the forceps, which may be justly regarded as the obstetrician's one or principal resource of potential aid, its proper conformation—in accordance with anatomical and physiological requirements, that its use may not be restricted while its injurious effects may be avoided—is an object worthy of most careful study.

As the site of the most frequent injuries resulting from the use of the forceps is at the vaginal outlet, and especially at the perineum, that portion of the instrument which bears most severely upon this region (in

our efforts to form a model that shall act non-injuriouly) should receive our first or principal attention.

That section of the instrument which comes into most severe contact with the vaginal outlet—that unnecessarily stretches it as a whole, or presses upon and severely stretches the perineal commissure—is its shank, near its junction with the blades. The indications to be followed in the construction of this portion of the shank are: (1) to avoid bilateral distension of the ostium as a whole, and (2) to avoid making pressure upon the perineal edge. In the model here offered the first indication has been met by bringing the shanks at once, at their very commencement, into apposition, while the second has been equally well met by giving to the closely applied shanks an upward bend or curving, by which the elevation of an inch above a base or straight line at its highest point is gained. This upward curve is accomplished without thereby altering the line of traction for the forceps, or in any way impairing its introduction or application, while the relief it affords to the perineal edge is very great.

As these two features affect the same portion of the forceps and supplement each other in their conservative action, they may be considered in connection, and their utility thus more clearly shown. Every operator must have noticed, while using instruments having widely separated, divergent, and straight shanks, that such shanks, emerging from the vagina and coming down with the advancing head, caused more or less severe bilateral stretching of the vaginal os, and, especially when making traction backward and downward, more severely put its posterior commissure upon the stretch.

Operating never so carefully with an instrument having shanks as set forth—as they are constructed in many of the

forceps in most common use, and notably in the Elliot, Simpson, Taylor, and Tarnier—one can not avoid making painful distension of the vaginal outlet, or so stretching and making pressure upon the perinæum as to test the resistant tension and strength of that body severely, or even cause its slight rupture. And where there exists either of the following conditions—one or more of which are very likely to be present in nearly every forceps case—namely, a small, unyielding, or sensitive os vaginæ; an intact ostium, not previously ruptured; an os elevated and tensely stretched, as it is generally found to be when the forceps is required, caused by the distension and strain put upon the entire vagina by the presence of the passing head, and by the traction which is being exerted through the vagina upon its outer attachments by the uterine expulsive contractions; an intact perinæum, or an unusually long perinæum; or a position of the head high up, with the perinæum normal—the difficulty set forth is so far increased, and straight separated shanks act with correspondingly augmented severity.

As the pain caused by stretching an already taxed ostium is exquisitely severe, and its occurrence so far detrimental to the nervous tone of the woman; and as the stretching and pressure exerted by imperfect shanks upon the perineal edge, when such is elevated and tense, probably cause some slight rupture of its anterior fibers, which thereby initiate, at this early stage of labor, a later, more complete or entire *but possibly otherwise preventable laceration* of that body when, as the head extends and the face sweeps out, or the shoulders are hastily brought forth, and the final strain of delivery occurs—these results, if they are unnecessary, as I hold them to be in the main, constitute the strongest reason for such relief as can be afforded.

In a great degree, and so far as they can be, these indications are met in the construction of the shanks in this model as given.

Being brought into close apposition throughout, they must emerge from the vagina as one piece, and hence can not cause any degree of bilateral stretching of that outlet; and, being at once elevated away from and above the perinæum, they can not bear heavily upon that body, no matter in what direction traction is made with them.

The indication for a *shortened cephalic curve*, especially anteriorly, which is accomplished in this instrument by a quick approximation of the blades proper from their point of greatest separation to their termination in the shanks, is readily seen. Such curve naturally will follow the contour of the child's head more closely, and thus constitute the minimum of an additional distension by the instrument, which is so far an advantage. Furthermore, a shortened cephalic curve for the blades, which if complete brings the shanks into immediate apposition, not only relieves the vagina in a general way, but for its outlet, where, as stated, the injurious effects of forceps are mostly experienced, such a form for the blades especially accomplishes a conservative result. This is evident from the following, namely: A shortened cylindrical body with a diameter sufficient to cause its marked distension will traverse an organic, elastic, and contractile tube or canal more readily than a longer cylindrical body having an equal diameter throughout. The explana-

tion is that such a canal adapts itself and accomplishes its relief in each case in proportion as its entire structure is disengaged. This illustrates the utility of a short diameter, and hence a shortened cephalic curve for the blades as regards their general effect on the entire canal.

Furthermore, it has been observed that the outer portion of the vagina, and particularly its os, is to be found elevated and tense in the earlier stages of labor, when the forceps generally is required. The causes of this state of tension and elevation occurring at this time, which condition it should be noticed disappears as labor progresses—facts not before noticed, that I am aware of—and is quite relieved when the head reaches and rests upon the floor of the pelvis, have been set forth as distension of the entire vagina by the head, and as due to the expulsive traction which is being exerted through the canal. If, however, when this state exists, we apply a forceps having blades with long cephalic curves, which otherwise cause no greater distension, we shall see that at once we decidedly increase the conditions. Therefore, not only traction and distension, as set forth, possibly, but a *lengthened distension* especially adds to the strain upon the entire vagina, and particularly upon its outlet.

These considerations, then, illustrate the fact that the cephalic curves for the blades should, in order to provide against their causing unnecessary stretching, be as short as possible, and yet be adequate to grasp the head. Hence the value of this model in this respect.

The object of giving to the blades a *well-marked pelvic curve* is manifest from the facts: (1) such curve more nearly conforms to the shape of the pelvis and vagina, and hence is more readily introduced in its course, especially, when desired, into the higher positions; (2) the blades are more readily applied to the head in the higher positions, which they grasp perpendicularly, not diagonally, which is an advantage; (3) they are more readily locked in all the required positions; and (4) if such blades are narrow, antero-posteriorly, they are less liable, while traction is being made, to be dragged heavily against the surrounding parts.

It will be observed, in addition, that this decided pelvic curve is continued at its lowest point upward by the ascending portion of the perineal curve into the shanks. This form gives to the lower outline of the blades and shanks a circular sweep and quick elevation at the termination of the former, and thus permits of retaining the forceps in position and continuing traction with it until the head is drawn well down into the pelvis against the perinæum, without necessarily bringing the shanks against that commissure, as no other form of blade does; and constitutes an advantage of importance in its favor.

Furthermore, on account of the relief gained by the low position to which this form of forceps may be made to act by the approximated handles, and by the perineal curve, such downward traction may be made with this instrument, in accordance with the higher positions, as will enable the operator to accomplish with it all that is stated can be done with the elaborate Tarnier forceps, which instrument is objectionable—because of its weight, its long cephalic curves, its widely separated shanks, and its unwieldy, com-

plicated traction apparatus. The shortened handles of this forceps, which in addition are bent upward, are advantageous in permitting of a more ready use of the instrument upon the bed without in some cases being compelled to bring the woman's buttocks to and over its edge, or even to uncover her—procedures which are always unpleasant, but are invariably rendered necessary where the handles are long, or where, as in the Hodge, Wallace, or White instruments, they are bent downward.

This forceps, as finished by Messrs. Tiemann & Co., is light and attractive in appearance. It has the simple post and spring-catch lock, the post of which is cone-shaped and easily engaged. When closed, this lock firmly connects the two blades, preventing slipping, and, from the simplicity of its action, is readily detached when occasion requires.

The hand-pieces are of hard rubber, burned on, making a close junction which will not catch septic material. The blades, as constructed, though light, I have found sufficiently unyielding to retain their hold upon the head while any necessary or prudent degree of traction is being made. Whether as at present manufactured, however, as to weight and strength, and as to the degree given to the several curves, the instrument is as complete as may be, experience with it will determine. But that its essential features—the perineal curve, close apposition of the shanks, and shortened cephalic curve—will prove advantageous, I have no doubt.

Book Notices.

A System of Human Anatomy, including its Medical and Surgical Relations. By HARRISON ALLEN, M. D., Professor of Physiology in the University of Pennsylvania, etc. Section V, Nervous System. Philadelphia: Henry C. Lea's Son & Co., 1888. Pp. iv-459 to 683, inclusive.

THIS section of Dr. Allen's work is an excellent one in some respects, if viewed from the standpoint from which it was written. It has, however, serious defects. It is not an exhaustive work upon the subject, and some important omissions have struck the reviewer, especially in those pages which treat of the brain and the spinal cord. It is, perhaps, sufficiently full to satisfy the anatomical requirements of the medical practitioner and the surgeon, but it will add little to their physiological knowledge. It is a pleasure to the reviewer to compliment the author and the publishers upon the illustrations of this section. They are clear and distinct. The tints employed bring out the outlines of the nerves with unusual clearness. Some of the dissections are new, and the woodcuts are worthy of all praise.

We have noticed that authors' names are occasionally misspelled, and their contributions misquoted in a few instances. Some of the brain sections closely resemble those of Flechsig and others, and yet no credit is given. Figs. 93, 96, and 117 to 121 are either duplicates or close counterparts of familiar sections found in the works of the later investigators in nervous anatomy. It strikes the reviewer with surprise that the physiological functions of the "motor area" of the cerebral cortex should have been excluded from a "practical" work; that the corpus striatum and the optic thalamus should have but one page devoted to them, no mention being made of their probable functions; that the "internal capsule" of the brain should be

likewise deemed unworthy of physiological consideration; and, finally, that the entire subject of the anatomy of the brain and spinal cord should be crowded into a space of forty-eight pages—of which at least one fifth is occupied by cuts.

It is evident that the author did not write this section of his work from the clinical standpoint. If contrasted with some works which have lately been published upon the nervous system, the omission of physiological information detracts greatly from the interest of this section of Dr. Allen's work. It is in direct antagonism to the plan of the system as announced upon the title-page: "Human Anatomy, including its Medical and Surgical Relations." Descriptive anatomy of the nerve-centers is rendered practical only when the physiology of their component parts is stated. Then the bearings of anatomy upon nervous symptoms become intelligible to the general reader. Without a knowledge of the functions of the cerebral ganglia, the cortical centers, the columns of Turck, Goll, and Burdach in the spinal cord, etc., the medical practitioner fails to see the utility of anatomical information.

The author himself acknowledges the justness of this criticism when he incorporates the varieties of hemianopsia under his "practical remarks" upon the optic nerve, as well as in many other sections. Why he should have deemed it unnecessary to discuss cerebral and spinal physiology except in scattered paragraphs of the text which treats of the individual nerves is a puzzle.

How is it possible for a medical reader, with limited anatomical and physiological information, to grasp the true significance of such symptoms as anosmia, hemianopsia, bulbar paralysis, "Robertson's pupil," monoplegia, hemiplegia, paraplegia, anæsthesia, delayed sensation, the modifications of the superficial and deep spinal reflexes, and the electrical reactions of muscles, without a carefully prepared digest of both physiology and anatomy combined as his guide?

Chemistry: General, Medical, and Pharmaceutical, including the Chemistry of the U. S. Pharmacopœia, etc. By JOHN ATTFIELD, F. R. S., etc., Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc. Tenth edition, specially revised by the author for America. Philadelphia: Henry C. Lea's Son & Co., 1883. Pp. xvi-13 to 727, inclusive.

The Medical Student's Manual of Chemistry. By R. A. WITTHAUS, A. M., M. D., Professor of Chemistry and Toxicology in the University of Buffalo, etc. New York: William Wood & Co., 1883. Pp. xi-370.

ATTFIELD'S Chemistry is so well known as to be almost a standard, and, for those who wish to approach the science from the standpoint of the analytical chemist and the pharmacist, no better manual can be recommended. The present edition (the tenth) has been conformed to the United States Pharmacopœia, and in other respects fully brought up to date.

Of quite a different character is the recently published "Witthaus's Manual of Chemistry." It approaches the subject at once from a theoretical standpoint, beginning with the atomic theory and the principles upon which chemical formulæ are constituted; and throughout it constantly places the laws and general facts of the science prominently in the foreground. The properties of the individual elements and compounds are described, to be sure, but mainly as illustrative of the general principles; and the whole plan of the book is such as to give its reader a thorough grounding in the science of chemistry, just as Attfield's book directs his attention to chemistry as an art. The book certainly satisfies a need; and, in our opinion, it satisfies that need very well.

The definitions are excellent, the enunciation and explanation of theories admirable, and the classifications, although artificial, as all systems of chemical arrangement must be, are convenient and satisfactory enough. It is the sort of book, in short, that we should like to recommend to the student as the basis of his future study, being assured that, if he has well mastered its contents, he can subsequently encounter any of the larger technical treatises without fear of bewilderment.

The Field of Disease: A Book of Preventive Medicine. By BENJAMIN WARD RICHARDSON, M. D., LL. D., F. R. S., etc. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. 737.

THIS is a book that will surely find a place on the table of every progressive physician, although originally intended for popular reading alone. The work, however, seems too full and exhaustive to meet with ready sale to the public, who much prefer, when selecting a work on sanitary topics, to choose one of smaller dimensions; but to the medical profession, whose duty is now recognized to be quite as much to prevent as to cure disease, the book will be a boon. We do not agree, however, with Dr. Richardson that "the conception that these afflictions can be prevented is of modern times, and indeed we may say practically of the present century, or even of the latter two thirds of the present century." Has Dr. Richardson forgotten the search, centuries long, for the universal panacea? or the famous Code of Health of the School of Salerno? or yet the march of Ponce de Leon? Let us say that no age has been without its attempt at preventive medicine; the present is only its most successful epoch.

This subject, a tempting one to the reviewer, is too great to be disposed of satisfactorily in a few lines, and we must go on to examine some of the special features of the work. It is divided into three books. Book 1, in three parts, contains a running description of diseases, general and local, taken up according to the nomenclature of the London College of Physicians. Book 2, also in three parts, is on acquired diseases, and the induced or acquired diseases from inorganic poisons, gases, vapor, organic poisons, dusts, mechanical pressure on the lungs, concussions and shocks, overwork and strain, deformities and defects of body, physical injuries, surgical operations, mental agencies, moral agencies, mental shock, moral contagion, hysterical emotion, common emotion, and habit. The third book is in two parts, and is a "practical summary of the origin, causes, and prevention of disease."

In conclusion, it may be said that the book, although the work of an enthusiast, seems to fill a present want, and may well be viewed by its distinguished author as the first issue of the hand-book of that Eutopian "City of Hygeia" which all true lovers of the race desire to see.

We think, however, that in his next edition the author will doubtless find it expedient to shorten some of the topics in Book 1, and to elaborate that on the relationship of occupation to disease, pages 624 to 627. This chapter does not compare favorably with the classic work of Ramazzini and Patissier ("Maladies des artisans") published in 1822, which, for a book professing that all knowledge on this subject is extremely recent, is what Dundreary would call "a little off, you know"; but, where there is nothing to condemn and much to praise, we only criticise for the sake of the next edition.

BOOKS AND PAMPHLETS RECEIVED.

Practical Pathology. A Manual for Students and Practitioners. By G. Sims Woodhead, M. D., F. R. C. P. E., Demonstrator of Pathology in the University of Edinburgh, etc. With

one hundred and thirty-six colored plates. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xv-484.

A Manual of Obstetrics. By A. F. A. King, M. D., Professor of Obstetrics and Diseases of Women and Children in the Medical Department of the Columbian University, Washington, D. C., etc. With fifty-nine illustrations. Second edition. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. 338.

Manuale Clinico Terapeutico sulla Impotenza Sessuale nell' Uomo dell Dott. W. A. Hammond, Prof. delle Malattie Mentali e Nervose nella Università di New York. Riduzione dall' Inglese del Dottor A. Rubino. Napoli: Giovanni Jovene, 1884. Pp. vii-102.

The Causation of Sleep. By James Cappie, M. D. Second edition, rewritten. Edinburgh: James Thin, 1882. Pp. xv-207.

On the Pathology and Treatment of Gonorrhoea. By J. L. Milton, Senior Surgeon to St. John's Hospital for Diseases of the Skin, London. Fifth edition. New York: William Wood & Co., 1884. Pp. viii-306. [Wood's "Library of Standard Medical Authors."]

The Parents' Medical Note-Book. Compiled by A. Dunbar Walker, M. D., C. M. London: H. K. Lewis, 1884. Pp. 26.

Hand-Book of Eclampsia, or Notes and Cases of Puerpera. Convulsions; comprising all the Cases which have occurred during the Present Century within a radius of several miles around Avondale, Chester Co., Pa., so far as can be ascertained. By E. Michener, M. D., J. H. Stubbs, M. D., B. Thompson, M. D., R. B. Ewing, M. D., and S. Stebbins, M. D. Philadelphia: F. Al Davis, Atty., 1883. Pp. 68.

Mr. Brodhurst's View of the Cause of Rotation in Lateral Curvature of the Spine. By A. B. Judson, M. D., etc. [Reprint from the "Medical Record."]

Is Extirpation of the Cancerous Uterus a Justifiable Operation? By A. Reeves Jackson, M. D., etc., Chicago. [Reprint from the "Transactions of the American Gynecological Society."]

The Surgical Treatment of Tumors and other Obscure Conditions of the Bladder. By Walter Whitehead, F. R. C. S. E., etc., and Bilton Pollard, M. D., etc. [Reprint from the "Lancet." Price, 1s.]

First Annual Report of the New York Skin and Cancer Hospital.

Twelfth Annual Report of the New York Free Dispensary for Sick Children.

Annual Report of the Directors and Medical Board of St. Michael's Hospital, Newark, N. J., January 1, 1884.

Female Hygiene and Female Diseases. By J. K. Shirk, M. D., Member of the Lancaster City and County Medical Society. Lancaster, Pa.: The Lancaster Publishing Co., 1884. Pp. 107.

Contribuzione alla Patogenesi della Pseudo-ipertrofia Muscolare. Per Gradenigo, Dott. Giuseppe (juniore), di Padova. [Reprint from the "Annali Universali di Medicina."]

Fifth Biennial Report of the State Board of Health of Maryland, January, 1884.

Thirtieth Report upon the Births, Marriages, and Deaths in the State of Rhode Island, for the year ending December 31, 1882. Prepared by Charles H. Fisher, M. D., State Registrar of Vital Statistics, etc.

Fourth Annual Report of the Newark Charitable Eye and Ear Infirmary.

On a New Mode of Operating for Fistula in Ano. By Edward W. Jenks, M. D., LL. D., of Chicago. [Reprint from the "Gynecological Transactions."]

Medico-Legal Society. Inaugural Address of President Clark Bell, Esq., etc., January 8, 1884.

Medical Department of Niagara University, Buffalo, N. Y. Announcement of Spring Term, 1884.

NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*Published by
D. APPLETON & Co.Edited by
FRANK P. FOSTER, M. D.

NEW YORK SATURDAY, MARCH 8, 1884.

BENEFICIARIES IN MEDICAL SCHOOLS.

THE law of supply and demand will always make itself felt at the last, even in matters pertaining to so mismanaged a business as the American method of recruiting the ranks of the medical profession. Hence, granting it to be consistent with public duty to do so, there is at present no urgent call to take up with the tactics of trades-unionism, as one of the speakers at the recent meeting of the Medical Society of the State of New York forcibly remarked in the discussion on the proposed laws for regulating the entrance to the profession in this State. The abundance of medical practitioners in this country, as compared with almost if not quite every other country, is a striking fact, and one that has been dwelt upon to the full extent of its pertinence. It has often been urged, without the least regard to the collateral fact, that our country presents conditions bearing upon the questions raised that are wholly different from those that obtain in other countries with which the comparison is made. The chief of those conditions is that the United States lack compactness, not only as to the territory at large, but also as to the individual sections. It is only in the large cities that a practitioner of medicine can see as many patients in a day as his European brother can; in the rural districts most of his time every day is taken up with the mere getting about from one to another. We grant that, making all due allowance for this consideration, it is to be feared that the ranks of the profession are being filled up too fast, both for its own interest and for that of the public. We are confident, however, that this fact will soon come to be recognized by the greater proportion of the young men who, as matters are now, suffer themselves to be deluded into the expectation of making a living easily by the practice of medicine.

While, therefore, we do not share the alarm with which many look upon the increase of the medical body, it can not be questioned that to stimulate this increase, to carry it still farther, and especially by devices which are in themselves debasing, should be opposed with all the force at the command of the profession. From this point of view, it seems to us, medical men all over the country should feel under obligation to Dr. David W. Yandell, of Louisville, for his vigorous denunciation of the practice of soliciting young men to become students of medicine as beneficiaries. The beneficiary system is open, we think, to very grave objections at best. The practice of medicine is getting to be more and more a calling in which something beyond natural aptitude and reasonable educational qualification is needed to make the prospect of material success at all inviting—in one form or another, capital is growing to be an element in the condition that conduce to success. To lure

young men, then, into a career in which they will almost necessarily find themselves handicapped from the start is what this solicitation of beneficiary students amounts to.

Moreover, as at present conducted, the business of educating men in medicine is one in which the teachers have a pecuniary interest—an interest that is perfectly legitimate. To all intents and purposes it represents capital invested. To rob this investment of its just power to give a return, by the cheap devices of trade competition, is ignoble and unworthy of toleration. This sentiment is very far removed from the narrow spirit that would make all colleges conform to a hard and fast rule as to fees; the latitude in the matter now countenanced, and nowhere opposed, seems ample to acquit the quasi-federation of the leading colleges of any aim at crushing out legitimate rivalry. Besides a considerable range in the matter of the fees for a course of lectures, it allows beneficiaries to be taken in the proportion of five per cent. of the classes. From the statements made in Dr. Yandell's article (a signed supplement to the February number of the "American Practitioner"), the conclusion seems unavoidable that at least one of our colleges is in the habit of exceeding the utmost stretch of decency in the matter of beneficiaries. The devices resorted to, as given by Dr. Yandell in the form of letters from various members of the faculty to young men of whose intention of studying medicine they seem to have become aware casually, if not as the result of something quite akin to the emigrant-runner's modes of canvassing, we do not hesitate to say are nothing short of disgraceful. Fortunately, so flagrant a violation of propriety will undoubtedly work its own cure—whether to the confusion of the offending college or to a change in its policy, is a question of small moment.

THE WASHINGTON OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

ON the 5th of October this society completed the first year of its existence, and on that occasion its president, Dr. Samuel C. Busey, gave an address which we trust will be widely read, for it contains matter that no general practitioner of medicine, and especially no one who practices obstetrics, can fail to profit by pondering. We are indebted to Dr. Busey for a copy of the address, in pamphlet form, reprinted from the February number of the "American Journal of Obstetrics."

The best work in American medical literature is getting to be more and more the work that is presented before medical societies in the form of papers, and we have several times called attention to the great superiority, in general, of the papers read before the special societies. Dr. Busey distinctly recognizes the wide field of usefulness that lies open before such societies, and, with him, we congratulate the Washington Obstetrical and Gynæcological Society upon its foundation and upon its successful entrance into this field. New York still leads the way in the matter of special societies, and, while we are not unmindful of the good work done at times in the large general societies of New York, as lately exemplified by the discussions on puerperal fever at the Academy of Medicine, it is to the influence of her

special societies that New York should ascribe almost the whole of what she receives credit for in current medical literature—leaving books out of account, of course.

There is scarcely a city of any considerable importance in the land that can not follow our example to advantage. Certainly, the founders of the Washington Obstetrical and Gynecological Society are amply justified, by the creditable achievements of their society during the first year of its existence, in having judged that its organization would prove of advantage to the profession in their city. Not only has it reflected credit upon Washington, but, by its proceedings having been published to the general profession, it has contributed to the enlightenment of obstetrical and gynecological practice wherever those proceedings are read. It is too apt to be the case, there is reason to think, that the physicians of small cities distrust their ability to sustain special societies with credit. The feeling is quite natural, we will allow, especially in regard to some of the narrower specialties, but, when it comes to such subjects as obstetrics and gynecology—the first of which, at least, no general practitioner can avoid—the ability to maintain a special society ought to be almost co-extensive with the capability of general society work in medicine. In the case of Washington at all events, we are convinced that even the stricter specialties might be entered upon by societies with very flattering prospects of success, especially when we remember the advantages the capital possesses by virtue of its being in a certain sense the center of resort for many of the bright minds that are to be found in the medical corps of the army, the navy, and the marine-hospital service. To point the pertinence of the latter consideration, we need only refer to the conspicuous success of the newly-formed Naval Medical Society.

The greater portion of Dr. Busey's address is devoted to a masterly consideration of a subject that is destined yet to claim the most rigid scrutiny from the American profession—the justifiability of craniotomy. In the past this sacrificial operation has counted for little in the actual personal study of obstetrics in America, for the reason, mainly, that American women have very rarely been found the victims of pelvic contraction to a degree calling for any thought of such a procedure. When, in exceptional instances, the conditions generally held to call for its performance have arisen, the decision has therefore had to be made on the strength of foreign (that is to say, British) doctrine, as found ready at hand in the textbooks, rather than on the basis of deliberate conviction. With the tide of immigration that keeps on setting to our shores, however, and with the *res angusta domi* that must in the natural course of events sooner or later prevail among us as well as among the people of older countries, pelvic deformities will become a matter of frequent observation rather than of mere hearsay; and we shall then be forced to work the craniotomy problem out for ourselves. It is fortunate that, in the mean time, the prevalent British practice has been in a great measure overthrown by the work of our Continental brethren.

The legitimate deductions from this work are forcibly put

by Dr. Busey, and we are firm in the trust that an operation by which, at best, only four lives are saved out of ten imperiled can never become a general resource among us. Not the least of the grounds for national congratulation in this matter lies in the reflection that laparo-elytrotomy—essentially an American operation—has undoubtedly served as a prime stimulus to the advances that have been made of late years in perfecting the life-saving alternatives of craniotomy. The recent revival of the Sigaultean operation of symphyseotomy does not in the least detract from the justice of this observation, but rather confirms it.

MINOR PARAGRAPHS.

THE ACADEMY OF MEDICINE.

If there is any institution in New York in which every member of the profession in the city should feel a personal interest, it is the Academy of Medicine, inasmuch as it aims at providing a library and reading-room, together with several other means for facilitating literary work by physicians. Since the library is open to the general public also, there would seem to be good reason for an extension of the interest in its affairs that has sometimes been shown by persons not of the profession. It is but a few years since the Academy took the bold step of buying the property now occupied by it, and it is probably within the knowledge of many of our readers that, in consequence of that step, it is still burdened with a mortgage. We are glad to be able to say that a fund is being accumulated with gratifying rapidity with which this incumbrance may be paid off, and particularly glad to learn that recently several considerable gifts have been made to the Academy to be added to this fund. Among them, we may mention one of \$1,000, by Dr. Horace P. Farnham, and one of \$225, by Dr. C. R. Agnew.

THE STATE EXAMINING BOARD AND THE SECTS.

SOME months since, commenting on the Erie County society's bill for the establishment of a State examining board, we expressed a doubt as to the acquiescence of the sects in the proposed *pro rata* representation on the board, and therefore as to the expediency of attempting to secure such acquiescence by making the representation proportionate. That we had good ground for this opinion appears from the recent action of the homeopathic State society in expressing its disapproval of all the bills that have come before the Legislature, and declaring in favor of an equal representation of the sects. It ought now to be plain to the new committee of our own State society that there is nothing to be gained by attempts to propitiate the sects.

MEDICAL WOMEN IN THE LAST CENTURY.

It seems that in the year 1735 the calendar of the city of Lyons contained a list of forty-three master surgeons and a list of thirteen widows of surgeons, the latter being allowed to practice. "Lyon médical," recording the fact, waxes facetious, quoting the custom as undoubtedly an exemplification of the old adage: *Quand le médecin n'y est pas, on s'adresse à la médecine*, and adding that several of the widows might justly have passed for true *succédanés* (*succès d'année*) by the mere fact of their survival.

NEWS ITEMS, ETC.

THE PLEURO-PNEUMONIA BILL has passed the House, with an appropriation of \$250,000 to provide for carrying it into effect. We have already given the main features of the bill.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 4, 1884:

DISEASES.	Week ending Feb. 26.		Week ending Mar. 4.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	11	5	10	7
Scarlet Fever.....	64	11	78	19
Cerebro-spinal meningitis....	5	5	3	3
Measles.....	39	3	41	4
Diphtheria.....	44	23	35	21

THE COLLEGE OF PHYSICIANS AND SURGEONS, OF BALTIMORE.—The annual commencement was held on Tuesday of this week, and diplomas were conferred on one hundred and twenty-seven candidates. The alumni association, now numbering over a thousand members, held its meeting the day before.

THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK will hold its forty-third annual commencement on Tuesday evening, the 11th inst., at the Academy of Music.

THE UNIVERSITY OF VERMONT.—The new building of the medical department, the gift of Mr. John P. Howard, was inaugurated with appropriate exercises on Thursday, the 6th inst.

THE PENDLETON PRIZE, being a gold medal, for the best literary work done during the year 1883 by any member of the New York Medico-Chirurgical Society, has been awarded to Dr. Henry B. Millard, for his work on Bright's Disease.

THE LATE DR. ELISHA HARRIS.—At a recent conference of prison officials, held under the auspices of the National Prison Association, memorial resolutions were passed relating to the death of Dr. Harris.

THE FOOT-AND-MOUTH DISEASE, according to consular reports, is prevailing in almost every county in England. A cargo of cattle lately landed at Portland, Me., from England, having been reported to have spread the disease in the neighborhood, the Secretary of the Treasury has asked the Secretary of State to instruct our consuls in Great Britain to satisfy themselves of the healthy condition of cattle to be shipped to this country before certifying invoices. *Per contra*, the British Government is reported to have prohibited the importation of cattle from Portland from February 27th to March 12th, inclusive, the disease having broken out among a lot of animals shipped from that port recently.

BROOKLYN APPOINTMENTS.—Dr. E. A. Lewis having been transferred from the Fire Department to the Police Department, it is reported that Dr. J. W. Fleming, heretofore assistant surgeon to the Fire Department, has been made surgeon, being succeeded in his former office by Dr. N. A. Robbins.

THE CONGRESS FÜR INNERE MEDICIN, according to the "Medical Times and Gazette," will be held this year in Berlin, from the 21st to the 24th of April, under the presidency of Professor Frerichs. Papers will be read by Dr. Hermann Weber, on School Hygiene in England, especially with reference to Infectious Diseases; by Dr. Rosenthal, on Reflexes; and by Dr. Goltz, on the Localization of the Functions of the Brain. There will be discussions on True Pneumonia, its Etiology, Pathology, Clinical Characters, and Treatment; on Poliomyelitis and Neuritis; and on Nervous Dyspepsia.

THE NEW YORK SKIN AND CANCER HOSPITAL.—The position made vacant by the resignation of Dr. Hunter has been filled by the appointment of Dr. J. E. Janvrin, with Dr. J. R. Goffe as his assistant.

A SANITARY CONVENTION will be held at Hillside, Mich., on the 17th and 18th of April, under the auspices of the State Board of Health.

THE "INTERNATIONAL REVIEW OF MEDICAL AND SURGICAL TECHNICUS."—As its name implies, this new quarterly journal is devoted mainly to depicting and describing new devices, for the most part mechanical, for use in practice. It is edited by Dr. Joseph H. Warren, Dr. Charles E. Warren, and Dr. Willard E. Smith, and published in Boston. The first number, dated January, 1884, gives promise that the journal will prove exceedingly useful.

"THE ANALECTIC" is the title of a new monthly journal edited by Dr. Walter S. Wells, and published by the Messrs. Putnam. The contents are made up of condensed abstracts, and the work is very cleverly done, as was to have been expected from Dr. Wells's former experience in this particular branch of medical journalism.

THE NEW YORK HOME FOR CONVALESCENTS.—We are pleased to note the continued usefulness and prosperity of this institution, as shown in the fourth annual report, recently issued.

THE SANITARY COUNCIL OF THE MISSISSIPPI VALLEY will hold its sixth annual meeting in Memphis, Tenn., on Wednesday, March 19th.

A SOUTHERN RETREAT FOR INVALIDS.—Dr. W. M. Chamberlain, of No. 68 West Fortieth Street, will be glad to give to any one desiring it the address of a refined family (residing near a large town in Georgia, on a sandy plateau seven hundred feet above the sea) in which some of his patients have found a winter home with unusual sanitary and domestic advantages.

THE CARTWRIGHT LECTURES.—Owing to the pressing nature of Professor Wilder's engagements, together with his absence from town, his revision of the third lecture of the course is necessarily somewhat delayed. We are therefore compelled to defer its publication for the present.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 24, 1884, to March 1, 1884:*

BROWN, JOSEPH B., Lieutenant-Colonel, and **BILLINGS, JOHN S.**, Major, Surgeons. Directed to attend the International Health Exhibition in London, and, as delegates, the International Medical Congress at Copenhagen, to be held in May and August next, respectively; also to include Berlin in their route to or from Copenhagen, and to be governed by special instructions from the Surgeon-General in complying with this order. S. O. 44, Par. 8, A. G. O., February 21, 1884.

WOODWARD, JOSEPH J., Major and Surgeon. Leave of absence still further extended six months on account of sickness. S. O. 44, Par. 11, A. G. O., February 21, 1884.

HORTON, S. M., Major and Surgeon. Having reported at these headquarters from leave of absence, ordered to Fort Hays, Kansas, for duty. S. O. 40, Par. 2, Headquarters Department of the Missouri, Fort Leavenworth, Kansas, February 20, 1884.

DIETZ, WILLIAM D., First Lieutenant and Assistant Surgeon. Assigned to temporary duty at U. S. Military Academy, West Point, N. Y.

PHILLIPS, JOHN L., First Lieutenant and Assistant Surgeon. Assigned to temporary duty in Department of the East.

MEARNS, EDGAR A., First Lieutenant and Assistant Surgeon. Assigned to duty in Department of Arizona.

KNEEDLER, WILLIAM L., First Lieutenant and Assistant Surgeon. Assigned to duty in Department of Dakota.

BLACK, CHARLES S., First Lieutenant and Assistant Surgeon.

Assigned to duty in Department of Texas. S. O. 46, Par. 1, A. G. O., February 25, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending March 1, 1884:*

WHITAKER, H. W., Assistant Surgeon. Relieved from the Portsmouth and placed on sick leave.

GREEN, E. H., Passed Assistant Surgeon. Relieved from Museum of Hygiene, and waiting orders.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, March 10th:* New York Academy of Sciences (Section in Chemistry and Technology); New York Ophthalmological Society (private); New York Medico-Historical Society (annual—private).

Tuesday, March 11th: New York Surgical Society (private); New York Medical Union (private); Jersey City Pathological Society; Newark (N. J.) Medical Association (private); Trenton (N. J.) Medical Association (private); Medical Societies of the Counties of Chemung and Rensselaer.

Wednesday, March 12th: New York Pathological Society; American Microscopical Society of the City of New York; Medical Society of the Counties of Montgomery, N. Y., and Middlesex, N. J.

Thursday, March 13th: New York Laryngological Society (private); Society of Medical Jurisprudence and State Medicine; Harlem Medical Association (private); Brooklyn Pathological Society.

Friday, March 14th: Medical Society of the Town of Saugerties.

Proceedings of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of February 13, 1884.

GEORGE F. SHRADY, M. D., President, in the chair.

AN OLD INJURY OF THE LOWER LIMB.—Dr. F. FERGUSON reported further regarding a specimen presented at the last meeting of the society, which consisted of a lower limb removed from a man who had sustained an injury twenty years ago, for which he was treated in Paris. When the soft parts were removed from the bones, the result of an old injury was disclosed, by which the shaft of the femur seemed to have been driven down upon the condyles. The inner condyle had united with the shaft by bridges of bone, while osseous union had not taken place between the outer condyle and the shaft. There was a limited amount of motion, not so much in the joint itself as in the line of fracture between the outer condyle and the shaft and between the inner condyle and the articular surface of the tibia. There seemed also to have been an injury to the upper part of the bones of the leg, and they had become generally fused together by osseous material. There were also a number of sesamoid bones in the neighborhood of the knee. Some surgeons who had examined the specimen thought there had probably been slight arthritis deformans.

STRICTURE OF THE URETHRA; DILATATION AND HYPERTROPHY OF THE BLADDER AND URETERS; HYDRO-NEPHROSIS.—Dr. FERGUSON also presented specimens showing these conditions, removed from a man who had died in the Emigrants' Hospital, and for whom he was indebted to the superintendent of that institution. The man had first complained of difficult micturition, and three months afterward had entered Guy's Hospital, London, where he was told that he had a stricture of the urethra which would require constant attention, and was instructed

how to pass an instrument. Six months after his discharge he entered St. Bartholomew's Hospital, where he was told that an operation would be necessary, but he refused surgical interference. When he entered the Emigrants' Hospital in New York he was suffering intense pain, and the bladder was found to reach considerably above the symphysis pubis. The patient denied having had gonorrhœa or any injury to the urethra, and said that he had no reason for concealing venereal disease if he had ever so suffered. He positively refused any surgical operation whatever, and died a few days after admission, without any relief from the pain. At the autopsy three tight strictures were found just anterior to the prostatic urethra, two of which were impervious. Back of the strictures the urethra was largely dilated. The bladder and the ureters were largely dilated and thickened, and the kidneys were in a marked degree the seat of hydro-nephrosis.

CARCINOMA OF THE CARDIAC END OF THE STOMACH AND OF THE ESOPHAGUS.—Dr. FERGUSON also presented a specimen illustrating this condition occurring in a woman forty-three years of age, who was admitted to the service of Dr. A. B. Ball, at St. Luke's Hospital, on the 1st of August, 1883. The patient had suffered from pain in the epigastrium and back, which was aggravated by the presence of food in the stomach. Subsequently there was vomiting. When admitted to the hospital, although fairly well nourished, she had lost flesh to a marked degree, her appearance was cachectic, and she suffered constant pain in the back and epigastrium. All solid food was rejected by the stomach. She had hæmatemesis, at one period recurring repeatedly every day for three weeks. Nourishment was given principally by the rectum. A diagnosis of cancer of the stomach was made. She died on the 29th of January, 1884. Full one third of the cardiac portion of the stomach was found ulcerated, the ulceration also involving the lower end of the esophagus. There were no enlarged glands in the neighborhood of the growth, and no secondary deposits in other organs.

Dr. C. C. LEE thought, with reference to the second specimen, that the patient's statement to the effect that he had never suffered from gonorrhœa might under the circumstances be accepted as true, for the foundation of strictures in that region was often laid during boyhood, before exposure to gonorrhœa, the result not becoming manifest until later in life. Some years ago, when surgeon to the Venerable Department in Charity Hospital, he saw many similar cases of stricture, and this was only another which went to show the necessity of a timely operation.

PUERPERAL FEVER.—Dr. LEE exhibited a uterus removed from the body of a woman who had died of puerperal fever, in order that he might have an opportunity to make some remarks regarding the treatment of that disease, which of late had given rise to so much discussion in the medical societies of this city. The patient was a primipara, who was confined in the Maternity Hospital of the New York Foundling Asylum on the 1st of February, and who died on the 9th. The result of the autopsy, which was made by Dr. Northrup, would be given very briefly. The perineum was slightly ruptured, and was secured by one suture. Nothing unusual was observed in the condition of the patient until the fourth day after delivery, when she began to appear generally very ill, there being headache, pallor, and pain and tenderness in the lower part of the abdomen, most marked in the left iliac region. The lochia then assumed for the first time rather a fetid odor. On this day the temperature rose as high as 104° F., and the pulse was about 130. On the following day the temperature in the morning was 104°, and in the evening 104.5°. As on the first day on which the patient began to manifest these symptoms, they were supposed to be possibly due to milk fever. The treatment by intra-

uterine injections was, however, begun at once, and was continued up to the day of her death, which occurred four days later. Bichloride of mercury, one part to two thousand of water, was employed. At first the injections seemed to have a decidedly beneficial effect, reducing the temperature from 104.5° to 102° ; but subsequently, although they brought away a quantity of foetid debris, granular in character, and not at all membranous, they ceased to have any effect whatever in reducing the temperature or in controlling the course of the disease. He would not consume the time of the society by reading the daily temperature record. At the autopsy the abdomen was found distended, and there were the results of a perimetritis and an endometritis. There were no signs of cellulitis. The uterus contained brown, dirty-looking matter, irregularly heaped up on the lining membrane, and diffusing an offensive odor. This substance seemed to be due to broken-down clots, as no evidence of placental structure or membranes was to be seen. At one point on the cervix there seemed to be some indication of contusion; but the labor had been normal. There were no inflammatory products within the cervical area. The other abdominal organs were normal. In the absence of a microscopical examination, the endometritis seemed to have been croupous.

Dr. Lee remarked that the uterine douche had been given by an experienced house surgeon, and in the most careful manner, yet, beyond bringing the temperature down to 102° for the first two days, it had not produced the slightest amelioration of the symptoms. He did not mean to say that this case proved that the douche should not be administered when puerperal septicaemia was present. The systematic use of intra-uterine injections in puerperal septicaemia was an admirable and a necessary adjunct in the treatment of this affection; but he thought the laudation which it had received of late at the hands of some eminent obstetricians was liable to mislead others who had not had an equal experience in the treatment of this affection, and lead them into the erroneous supposition that this was the only thing which could be done. Here was a case in which the test was made of treatment almost exclusively by carefully conducted antiseptic intra-uterine douches, the patient dying, notwithstanding, at the end of a few days. The case did not prove, however, that this method of treatment was not highly important and valuable; but it certainly did show, as just stated, that it could not be relied upon alone for checking the process even when it was begun with the initial symptoms of septicaemia. Dr. Lee showed two forms of glass tube by which to make the injections, and stated that he found the curve of the hard rubber tube employed in Vienna to be better adapted to these cases, the greatest objection to that tube being that the bulbous distal end was screwed on to the shaft, thus being more liable to retain septic matter.

Dr. A. JACOBI thought that the septic process had probably got well under way before the injections were begun. This was indicated by the high temperature. Had they been given earlier they might have done more to control the disease. Often the diphtheritic form of inflammation after childbirth commenced with a low temperature, and might run its entire course without giving rise at any time to much elevation of temperature. Concerning the tubes through which to make intra-uterine injections, he had often thought that those made of glass were objectionable simply because they could not be bent to suit the varying axis of the uterine canal as it was found after labor. He therefore had been in the habit of using a large-sized, thick elastic rubber catheter, withdrawing the wire by degrees as the tube was introduced into the uterus, and thus making sure that it adapted itself perfectly to the direction of the canal without doing the least injury. So far as difficulty of cleaning the cath-

eter was concerned, he thought that if we could expect to disinfect the uterus in the living woman we certainly should be able to disinfect a large elastic catheter. He always used the fountain syringe.

Dr. LEE said it was true that the intra-uterine injections were not begun in this case until the fourth day after labor, but it was also true that the patient showed no signs of any abnormal state until that date, and he supposed that Dr. Jacobi would not begin the use of such injections until there were some indications for their use. He presumed that it was possible that the septic process might have got well under way before the injections were begun, but this measure could not be justified until certain symptoms dependent upon it had developed.

Dr. JACOBI said he had not intended to criticise the treatment in the case related by Dr. Lee. He had simply intended to say that in some cases it would be found that the septic poisoning had gone too far to be checked by the douche, and he was willing to admit that there were some cases in which he could not make the diagnosis until after it was too late to save the patient's life.

Dr. W. P. NORTHRUP said that, regarding the exudate on the lower half of the uterus, whatever name were applied to it, it was pus and fibrin. It had indifferently the names diphtheritic and croupous inflammation. The teaching in the College of Physicians and Surgeons was that, anatomically, the two lesions were the same. In diphtheria the specific systemic poison was accompanied by the local lesion. Dr. Lee was sustained by Dr. Delafield in calling this a croupous endometritis.

IMPERFORATE ANUS.—Dr. NORTHRUP presented the specimen, which was removed from a child who died on the eighth day. It had been brought to the Foundling Asylum and sent out to nurse. After a little time the nurse returned with the child, stating that it vomited after each nursing, was irritable, and had had no passage. The abdomen was found to be very much distended and the superficial veins much enlarged, as if the patient were suffering from cirrhosis of the liver. Externally the anus appeared normal, but, on inserting the little finger, it entered what appeared to be a *cul-de-sac*, and came in contact with a soft membrane. This was penetrated, as was also a thin imperforate membrane above, and a considerable amount of gas and feces afterward escaped. The child was much relieved, but, apparently without sufficient reason to account for it, it died on the eighth day. At the autopsy it was found that the finger, just after entering a *cul-de-sac* inside the lower sphincter, had penetrated a thin membrane, passed through some loose connective tissue, and just above had come in contact with a second membrane, stretching across and occluding the gut, which, when divided, had permitted the escape of the intestinal contents.

GENERAL CONNECTIVE-TISSUE HYPERPLASIA.—Dr. JACOBI presented a series of specimens taken from the body of a child who died in Bellevue Hospital at the age of between one and two months. The child had entered with its sick mother, and had presented no special symptoms, but died suddenly. The history was therefore very imperfect. At the autopsy nearly all the viscera were found to present the same lesion, a condition of interstitial-tissue hyperplasia. On the left side there was a pharyngeal abscess. Attention had not been called to any change in the child's voice. In the neighborhood of the abscess there were enlarged glands, and it was probable that the abscess began as a suppurating adenitis. The bronchial, mediastinal, and mesenteric glands were considerably enlarged. The left lung was the seat of slight hypostasis and emphysema; the right presented interstitial pneumonia. The liver was enlarged, heavy, and pale, and its surface presented thousands of little dots. It was cirrhotic, containing a large amount of new

interstitial tissue, and in a less degree it was fatty. Both kidneys were the seat of interstitial nephritis, the change being more marked in the left than in the right organ. The spleen, although it had not yet been examined microscopically, seemed also to have undergone a like pathological change. The walls of the lower third of the small intestine were swollen and thickened, and at a few places had undergone ulceration. Nothing abnormal was found in the brain. Nowhere were gummata present. It was probable we should have to fall back in the aetiology upon some general cause, probably syphilis. Gummata were not so frequent in the infant affected with hereditary syphilis as general hyperplasia of the tissues.

Dr. J. Lewis Smith believed that peripharyngeal abscess occurred more frequently in New York than was commonly supposed, being due to a strumous state of the glands, and, if recognized in time, life might be saved by an operation.

STRICTURE OF THE ESOPHAGUS CAUSED BY A CARCINOMATOUS GROWTH.—Dr. BEVERLEY ROBINSON presented the specimen, which was removed from the body of a man who died at forty-two years of age, having suffered from a profuse muco-purulent expectoration for six months previous to his admission to the hospital; also from frequent vomiting, considerable dyspnoea, and loss of flesh. The case was interesting from the fact that, notwithstanding the extent and degree of the obstruction to the lower portion of the oesophagus by the carcinomatous growth, the patient did not complain of pain on deglutition until two weeks prior to death. He did not vomit during the three weeks he was in the hospital. There were certain physical signs present which had led to a mistake in diagnosis, and which Dr. Robinson did not think appeared perfectly clear in the light of the autopsy.

AN OSTEOTOME.—Dr. J. A. WYETH presented a modification of the osteotome of Mr. Gowan, of Guy's Hospital, London, and said that he regarded it as the most useful instrument in his armamentarium. It consisted of a saw in the shape of a chisel, connected with two horizontal spring jaws, intended to hold the bone; the saw, being in position, was worked laterally, in a semicircle, by the right hand, while the bone was steadied with the jaws held by the left hand. Dr. Wyeth had used the instrument in excision at the hip joint once, at the shoulder joint twice, at the wrist joint once, at the elbow joint once, at the ankle once, and on the scapula, besides at some of the smaller joints, and it had given great satisfaction. He had divided the neck of the femur with it in one minute. The instrument as modified by him was less complicated and less costly than the original.

NEW YORK ACADEMY OF MEDICINE.

Meeting of February 21, 1884.

FORDYCE BARKER, M.D., LL.D., President, in the chair.

THE DIFFERENCES IN FORM OF THE ADULT HEAD.—Dr. JOHN C. DALTON made some remarks upon this subject. He had lately become interested in a method of comparing the differences in the form of the adult human head by means of the paper patterns which hatters made in fitting hats. These patterns were made from models representing perfectly the circumferential outline of the head on a line with the hat-band. At one of the shops where he visited there were many of these patterns. It occurred to him, in looking them over, that there was a great variety in the forms presented, and he thought it might be an interesting way of comparing the forms of the adult head in persons mainly resident in the city, and all probably in comfortable circumstances, being able at least to employ a regular hatter. He had a quantity of these patterns, representing the shape of three hundred and sixty heads of customers as they

appeared in succession. Looking at the diagrams [of which nine were shown] representing some of the most decided variations in outline in a general way, there were certain variations which would strike the observer. First of all, as to general shape, it could be divided into the variations with which all were probably acquainted—into long heads and round heads. There was a great deal of variation within certain limits in this respect. It was considered that in the medium form of head the width stood in relation to the length in about the proportion of 100 to 125. Practically, however, the mean length ranged between 120 and 130, and, representing the width by 100, any head in which the length would be represented by a figure below 120 would be classed as a round head, and above 130 as a long head. Besides these peculiarities respecting width and length, there were also other peculiarities in form. In some cases the front portion of the head was narrower than the back portion, and *vice versa*. In some the entire outline was curvilinear, but in the great majority of cases there were angles and straight lines. Again, the two sides of the head were more or less unsymmetrical. In the first diagram there would be seen a very regular, symmetrical oval. In No. 2 there was a squaring of the frontal part of the head; the temples were flattened. This flattening of the temples existed in many cases, in some amounting almost to a depression, and such persons found difficulty in obtaining a well-fitting hat. In No. 3 the occiput was not so rounded. We now came to those which began to merge into the class of long heads. In one case the length was represented by 135, and in the longest of the lot the length was represented by 153. A general glance at the long head would give one the impression that the elongation consisted chiefly in a projection of the occiput. In the diagram most nearly round the length was represented by 108.

With regard to the want of regularity in the outline in the diagrams, it was present in all in greater or less degree. Although it might not be apparent to casual observation, it became very readily apparent when the diagram was folded in the median line along the long diameter. The edge of one half of the paper diagram would be seen to project irregularly beyond the corresponding part of its fellow. In some cases the want of symmetry was very pronounced, while in others it was very slight; but Dr. Dalton had not been able to find any in which there was perfect symmetry. This want of symmetry was also one of the first peculiarities which struck the observer in making successive sections of healthy brains, and was present whether the sections were made vertically, horizontally, longitudinally, or crosswise, and it pertained to both the cerebrum and the cerebellum.

These observations raised a question of some practical interest. We were now very strongly inclined to believe that all parts of the brain had not one and the same function or mode of action; that there were certain nervous operations conducted by the gray matter in one part of the brain, and other, different nervous operations by the gray matter in another part, even of the cortical substance; so that we had begun to localize in many instances, in a pretty distinct way, certain particular functions in certain particular convolutions, as, for example, the relation of the motor zone in the region of the fissure of Rolando to certain muscular movements. It was also pretty well established that these differences in function and mode of operation were connected with differences in structure; that the gray matter in the anterior and posterior cerebral convolutions possessed regions of nerve cells of different volume and different shape; that whole regions differed from other whole regions in this respect. The same thing was true in the perceptive centers. Dr. Dalton then asked the question: Suppose one examined a brain of which the two sides were very different in form; did

this not imply an exaggeration or a deficiency of certain parts of the brain that were endowed with special functions, and, consequently, differences in the operation of the nervous system? That would seem to be a very natural conclusion from these anatomical facts, and yet he was not at all sure that this conclusion was true. If we took a long brain and a round brain, and examined them, we should, in the first place, perhaps feel sure that the long brain had in it more gray matter in the cortical layer than the round brain had, because a sphere, of course, had a smaller extent of surface in proportion to its bulk than any other form of body. But it must be remembered that the brain did not present a perfectly smooth outline, but was convoluted, and the round brain therefore might have more extensive folding of the convolutions, and, consequently, present as great an amount of cortical gray matter as the long brain. Again, Dr. Dalton showed some skulls, one illustrating the long head and another the round head, and stated that the round head was higher, fuller in the coronal region, whereby it might gain in superficial area. He inferred that this difference in superficial outline at a given portion of two different brains, the one being flattened and the other rounded, did not indicate a deficiency in the former and an over-amount in the latter of special function; for in the former the corresponding convolutions might be shallow but wide, while in the latter they were deep and narrow. There might be the same physiological quality in a particular part of the gray substance, although its position might be varied and even shifted. These facts applied not only to differences in the shape of the brain in different individuals, but also to differences in shape in the two hemispheres of the same brain. As bearing upon this point, Dr. Dalton presented two Indian skulls, in which the form had been changed by the custom of compressing the yielding skull of the papoose, and compelling it while growing to assume a particular shape. It did not necessarily follow that in the one in which the forehead was greatly compressed there was none of that portion of the brain present devoted to intellect (assuming that the intellect had its seat in the anterior convolutions); or that in the other, compressed in the occipital region, there was no development of the posterior lobes and of the corresponding functions.

The President said that about fifteen years ago there was a good deal of discussion among obstetricians with regard to the influence of parturition in giving shape to the human head. He then instituted some investigations at Bellevue Hospital, carried out by the house staff, regarding the shape of the head at birth and for some time afterward. These investigations showed that the head of the infant, while being molded to pass through the pelvic canal, became flattened at portions where there was the greatest pressure, and filled out at portions where the resistance offered by the hard parts was least. For instance, if the occiput presented at the left ilio-pectineal eminence, and the sinciput at the right sacro-iliac synchondrosis, the corresponding diameter of the child's head would after birth be found to be shorter than the opposite diameter. By this means he had often been able to determine, when called in consultation within forty-eight hours after a child's birth, what had been the presentation. This peculiarity of shape gradually disappeared after the birth of the child. Whether it had more or less of permanent influence he was unable to say. There was another point which he hoped Dr. Dalton would be able in the future to develop. It related to the change in the form and size of the adult head at different periods of life. Dr. Barker felt quite sure that the head did continue to change even until late in life. This was noticeable in his own case, as was shown by the latter's measurements during the past twenty-five years.

Dr. J. L. CORNING had been very much interested in Dr.

Dalton's remarks, inasmuch as he had given a most accurate method for determining the form of the head, and especially as he had suggested that function depended upon whether the brain structure was absolutely intact rather than upon whether it presented a particular form. His remarks would show, for example, that pressure applied to the anterior portion of the head would result not in obliteration or atrophy of the brain structure below, but rather in pushing those parts in such a manner that they found room and place elsewhere. This question had its bearings upon another question to which considerable attention and importance had been given by some, namely, with regard to the influence of asymmetry of the skull upon soundness of the mind. Dr. Corning was not disposed to attribute much importance to this peculiarity in cranial outline.

Dr. DAVID WEBSTER thought the statement made by the President—that the adult head might change in form—would account for the fact that his hatter had been compelled to alter the pattern of his hat from time to time, although until this evening he had supposed this difference in size and outline was to be accounted for by a difference in the amount and distribution of the hair.

Dr. DALTON closed the discussion, and said the points brought out by the President were very interesting, and he was glad that attention had been called to them. He finished by saying that he thought we could not conclude certainly from asymmetry or a difference in external form of the adult head that there was a corresponding deficiency or enlargement of the brain underneath. It might exist, but it was uncertain.

AN IMPROVED METHOD IN THE TREATMENT OF CERTAIN FORMS OF SKIN AFFECTIONS.—Dr. P. ALBERT MORROW read a paper on this subject. The method of treatment indicated in the title of the paper consisted essentially in the application of medicinal substances to the skin in the form of fixed adhesive preparations, the object being to confine the application of the drug to the diseased surface alone, and to secure its continued action by long contact with the tissues by means of a practically immovable dressing. The means for carrying out this idea might be stated as follows: Applying the drug as a powder or paste, protected by a coating of collodion or other substance; by mixture with gelatin rendered soft and pliable by means of glycerin; by combining the drug in desired proportion with collodion or gutta-percha; by medicated gutta-percha mixtures applied on cloth cut into suitable forms for easy adaptation to the surface. The author did not presume to offer anything new to dermatologists, who were acquainted with these methods, but an explanation of these procedures might not prove uninteresting to the general profession. Although their introduction dated back one or two years, they might be regarded as substantially new, since they were not described in recent text-books on skin diseases. He did not claim anything original in connection with the method, but would endeavor to present, in as concise a style as possible consistent with clearness, the main features of its application, the conditions in which it was indicated, and the appreciation of its value based upon clinical results, derived partly from his own experience and largely from the experience of others. Few would deny that the introduction of the method marked a decided advance in cutaneous therapeutics.

Dr. MORROW first glanced at the appliances used hitherto for bringing medicines in contact with the cutaneous surface, such as powders, lotions, pastes, plasters, resins, and ointments. Their use was attended with certain disadvantages. For example, powders were easily rubbed off, and, when applied to exuding surfaces, they frequently formed crusts and aggravated the trouble; lotions evaporated, leaving the skin dry and brittle, causing uneasiness and distress; pastes and plasters were of limited application, and, because of their uncleanness, never

were popular; resins acted as irritants; ointments were generally regarded as the most convenient form, but they were easily rubbed off and absorbed by the clothing, and they were also uncleanly, and offended the taste of fastidious patients; again, they had not the consistence to exclude air and thus effectually protect the surface; it was difficult also to restrict the oleaginous substance to the seat of the disease. He did not wish, however, to detract from the real value and practical utility of these methods in some cases; indeed, they were often the most valuable means for cure, and could not be superseded by any other method.

The range of adhesive plasters also was not universal; on the contrary, it was comparatively limited. In many cases a non-localized eruption, a high grade of inflammation, or other features, rendered their application impossible.

Cutaneous pharmacy had not kept pace with methods for internal treatment, but among the valuable drugs with which it had become enriched were chrysarobin, salicylic acid, naphthol, etc. The difficulty in applying some of these to the skin by former methods had led to the invention of the improved methods of which the author would speak. The objectionable features of chrysarobin were its property of staining the hair, skin, nails, and clothing, its irritating effect upon the healthy skin, and the frequent production of erythema and erysipelatous inflammation. This had led Dr. Fox to limit the application of the drug by covering it, when mixed in a paste and applied to the skin, with a piece of gutta-percha tissue rendered adhesive by touching its edges with collodion. This method of application was tedious. Dr. Morrow then referred to the preparations brought forward or used by different physicians for the treatment of skin affections—Auspitz, Mitchell, Fox, Taylor, and others. Drugs mixed with collodion had the advantages of convenience for use, of cleanliness, and of remaining for some time upon the skin. Medicated gelatin, mixed with water and allowed to dry, could be kept for use. When applied to the surface it could be softened with hot water, and covered with glycerin to prevent cracking. Or it might be put up in rolls Auspitz claimed advantages for a solution of refined gutta-percha in chloroform, it being quite durable, elastic, drying more slowly than collodion, and thus admitting of more thorough application, qualities adapting it specially as an application to joints. Gutta-percha plasters constituted a decided improvement upon lead and resin plasters. They were very convenient for application to the diseased skin of the palms, the fingers, the toes, the inter-digital spaces, near the anus, etc. They should be cut into strips admitting of accurate adjustment.

After briefly referring to the advantage with which certain authors had made use of collodion and gelatin adhesive plasters medicated with chrysarobin, salicylic acid, carbolic acid, oxide of zinc, glycerin, etc., in the treatment of psoriasis, chronic eczema, prurigo, and other forms of skin disease, Dr. Morrow gave his own experience, and stated that he had experimented with the preparations in a variety of cutaneous disorders, and for the most part with satisfactory results. He had been enabled to use chrysarobin in psoriasis affecting the face and hairy scalp without danger of injury to the eyes or other delicate parts. In chronic forms of eczematous disease, and even in acute forms, he had used gelatin medicated with 10 per cent. of oxide of zinc with good results. He mentioned the case of a gentleman who had been affected for years with a chronic eczema of the face, genitals, and other portions of the body. The skin of the face was thickened and infiltrated, giving it almost an elephantiasis appearance. The itching was so great that the patient was unable to sleep. Various anti-pruritic ointments had failed to give relief from this troublesome symptom. A single application of gelatin medicated with 10 per cent. of oxide of zinc and 1 per

cent. of carbolic acid gave complete relief. The artificial cuticle began to crack from the drying of the application, and, after a few daily paintings, the fissures almost entirely healed. Over the eyelids the gelatin coating could not be applied, for obvious reasons, and here a bismuth ointment was applied. After a few days one could see the exact line where the gelatin application terminated. Above this line the skin was harsh, and presented its original characteristics, while below it was soft and healthy in appearance.

The author summarized the advantages of adhesive applications by saying that they afforded complete protection to the part to which they were applied and excluded the air; their fixation admitted of greater and more permanent action; by compression they modified the circulatory changes and limited exudation; and they were cleanly. They were of special benefit in cases of tendency to cutaneous hyperplasia from different morbid conditions, in overgrowth of the hard epidermis, in acne rosacea, in chronic eczema, in tinea capitis, in syphilitic lesions, in lupus, possibly in epithelioma, etc.

Dr. E. B. BRONSON particularly admired the conservative manner in which the author had alluded to these new remedies. They had, it was true, become the fashion. The chances were that their use would be overdone. They were suitable to certain classes of disease, and presented certain advantages over other forms of therapeutics. They were not, however, suitable as universal applications. He had experimented with most of the applications referred to, and had arrived at the conclusion that the gelatin preparations possessed comparatively little value. His own experience had been unfortunate. The collodion and gutta-percha preparations were much easier of application, and it seemed to him that they would in time entirely supersede the gelatin preparations. He had used them to a considerable extent, more particularly the gutta-percha preparations, and he could fully indorse all that had been said in their favor by Dr. Morrow. The diseases in which he had found them useful were those in which there was a certain degree of thickening. He did not think that their chief advantage was in their power to protect the parts, for the reason that, where it was desirable to do this, the remedies were not suitable, as they could not be applied sufficiently often. For instance, in eczema it would be necessary to change the application at very frequent intervals, and under those circumstances, although protection was of the first importance, a protective dressing which was fixed and could not be readily reapplied was rather objectionable. It was rather for the exact coaptation of the remedy to the parts that these applications were of special excellence. One advantage, especially in psoriasis, was the deliberate manner with which they could be applied. Gelatin preparations set too rapidly. In using chrysarobin in psoriasis it was specially necessary to rub it thoroughly in. With the gutta-percha solution of Auspitz that could be done. The chief advantage, however, was in that form of eczema in which there was considerable circumscribed thickening, with perhaps some itching. If it were desired to simply stop itching, the surface might be painted over with carbolic acid, putting over this a coat of gutta-percha protective.

Dr. GEORGE T. JACKSON had made use of these methods, and had found trouble in applying the gelatin preparations, and, besides, in the few cases in which he had used it, it caused more disturbance than the other methods. He referred to a form of long gelatin sticks which could be dipped into hot water and applied to the surface. With regard to the collodion preparations, he agreed with Dr. Bronson as to their value in psoriasis and chronic eczema.

Dr. SAMUEL SNERWELL, of Brooklyn, had not had much experience with these methods. He had made use of preparations of collodion with salicylic acid and chrysarobin, and with more

or less satisfaction. He could conceive how the gelatin preparations, as Dr. Bronson had said, might be inconvenient to use, and he thought that there would be many difficulties in the way of applying them to parts covered by hair. He could not see how they could be applied and kept on, and renewed, or, when applied, made as effective as unguents.

Dr. Morrow said the criticism which Dr. Bronson had made of the gelatin preparations might be perfectly reasonable from his standpoint, but he (Dr. Morrow) had not found any inconvenience in their use—that was, no more than the time requisite for heating them and for their application. He thought that their efficacy depended largely upon the exact proportions in which the gelatin, the glycerin, and the active ingredients were combined. For example, the first preparations which were made for him were defective, and, had he passed judgment upon the value of gelatin applications from his first experience, that judgment would have been very unfavorable. But repeated trials produced better results each time. Simply by adding a little water or a little glycerin, as he found to be necessary, the proper degree of consistence could be secured, and, when applied in this way, they certainly formed a perfectly uniform elastic coating, which remained perfect without cracking for several hours, depending upon the location and the degree of motion to which the part was subjected. As to Dr. Sherwell's objection to the application of gelatin to exuding surfaces, he had conceived the same objection theoretically, but practically there was not this objection. For instance, he applied it to a leg affected with eczema rubrum, and the next day it peeled off and there was great improvement; the patient said there was complete cessation of itching. He believed that, when the pharmaceutical processes involved in making the gelatin preparations became improved, they would give greater satisfaction. As to Dr. Sherwell's objection to their application to the hairy parts, he had the hair shaved off, and then found no difficulty in making applications containing chrysarobin, etc. There were certain other theoretical objections to the use of these preparations which had arisen in his mind, but which had not held true when he came to make use of them in practice.

Dr. W. M. CARPENTER then read some resolutions, which were adopted by the Academy, cordially indorsing the aims of the society whose object was to furnish first aid to the injured.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of February 6, 1884.

THE CLINICAL ASPECTS OF CEREBRAL SYPHILIS.—Dr. HORATIO C. WOOD read the following paper:

In the present article I propose to say very little in regard to the lesions of cerebral syphilis, only making such allusions as are necessary to the clinical study. So much practical importance attaches to the etiological relations of the disorder that I shall discuss these at some length. We do not know why syphilis attacks one portion of the brain rather than another in any individual case; indeed, very rarely can we give any sufficient explanation why the brain is affected at all.

It is naturally to be expected that any cause of ordinary brain inflammation would, when present in a syphilitic person, tend to precipitate a specific cerebral disease. Thus, as thermic fever frequently provokes chronic meningitis, much plausibility attaches to the report of a case in the "*Jour. de méd. et chir. prat.*," Paris, 1879, p. 291, where the cerebral syphilis is ascribed to a sunstroke. Blows and other traumatism would, in a similar manner, be supposed to figure largely as exciting causes of brain syphilis; but I have never met with a case having such relations, and reports of them are rare in literature.

The only records I have found are the cases reported by Dr. Broadbent ("*Lancet*," 1876, ii, p. 741), and a small collection in Huebner's article on Nervous Syphilis, in von Ziemssen's "*Cyclopædia*," xii, 301. I have seen two cases of presumably traumatic spinal syphilis—one in which a polio-myelitis* followed a fall on the ice, and one in which, after a fall from a cart and marked spinal concussion, a local myelitis developed. ("*Univers. Hosp. Dispen. Service Book*," x, 1875, p. 58.)

Various authorities attach much influence to overstudy and other forms of cerebral strain in exciting brain syphilis. Engelstedt is stated to have reported cases having such etiological relations, and Fournier ("*La syphilis du cerveau*") affirms that he has especially seen the disease in professional men and other persons habitually exercising their brains to excess. Neither in private nor in public practice have I met with any instance where over brain-work could be considered a distinct etiological factor, while the wards of the Philadelphia Hospital and the roll of the University Dispensary are full of cases occurring in persons who use not at all the modicum of brains nature has endowed them with. So far as my observation goes, cases of brain syphilis in which any exciting cause can be found are very rare.

The inherited diathesis is less prone to manifest itself in the nervous system than in other portions of the body, but it certainly is capable of causing every type of nervous disease that follows infection from impure coition.

As early as 1779 Dr. Jos. Glenck ("*Doctrina de Morbis Veneris*," Vienna) reported a case of a girl, six years old, cured, by a mercurial course, of an epilepsy of three years' standing, and of other manifestations of hereditary syphilis. Von Graefe found gummatous tumors in the cerebrum of a child nearly two years old ("*Arch. f. Ophthalm.*," Bd. i, erst. Abth.). Professor O. Huebner (Virchow's "*Archiv*," Bd. lxxix, 269) details the occurrence of pachymeningitis hæmorrhagica in a syphilitic infant under a year old. Dr. Hans Chiari ("*Wien. med. Wochenschrift*," xxxi, 1881, 17) reports a case in which very pronounced syphilitic degeneration of the brain-vessels was found in a child fourteen months old. Both Dr. Barlow ("*Trans. of the Path. Soc. of London*," 1877) and Dr. T. S. Dowse ("*The Brain and its Diseases*," vol. i, p. 76) report cases of nerve syphilis in male infants of fifteen months.

It is a matter of great interest to know how late in life nervous disease from inherited taint may develop. We have as yet little light upon the equally interesting and cognate problem as to how far inherited syphilis may produce late in life nervous diseases whose type is not distinctly specific, but it is probable that even after puberty specific nervous affections may appear for the first time in the unfortunate offspring of syphilitic parents. Mr. Nettleship reports ("*Trans. of the Path. Soc. of London*," xxxii, 18) the development of a cerebral gumma in a girl of ten years, and Mr. J. A. Ormerod ("*Ibid.*," p. 14) of a tumor of the median nerve (probably gummatous) in a woman of twenty-three, both the subjects of inherited syphilis. Dr. Thomas S. Dowse (*loc. cit.*, p. 71) details a case of cerebral gumma at the age of ten years, and Dr. Samuel Wilks ("*Lectures on Dis. of the Nerv. Syst.*," Philadelphia, 1878, p. 333) one of epilepsy from inherited taint in a boy of fourteen. Dr. J. Hughlings Jackson reports ("*Jour. of Ment. and Nerv. Dis-*

* In this case the man had symmetrical specific skin eruptions upon the arm, and the symptoms were peculiarly symmetrical; great coldness of both forearms; excessive sweating of the palms; loss of power, so much more pronounced in the extensors than elsewhere that the patient had been treated for lead poisoning and great wasting of the extensor muscles. Evidently a symmetrical syphilis chiefly confined to the anterior spinal cornua.

ease," 1875, p. 516) paraplegia with epilepsy in a boy of eight, hemiplegia in a girl of eighteen, and, in the "Brit. Med. Journal," May 18, 1872, hemiplegia in a woman of twenty-two, the nervous affection in each case being associated with or dependent upon inherited syphilis. Dr. E. Mendel reports ("Archiv f. Psychiatrie," Bd. i, 313) a case of a child who had inherited syphilis, and developed in her fifteenth year a maniacal attack with hallucinations.

Some time since I saw, in an orphan of fourteen, a chronic basal meningitis, and, in the absence of any history, gave the fatal prognosis of tubercular disease, but, to my astonishment, under the long-continued use of iodide of potassium, complete recovery occurred. No signs of inherited syphilis were perceptible, but the specific nature of the inflammation is, in view of the result, scarcely doubtful; it is probable that, in some of the reported cases of alleged recovery from tubercular meningitis, the affection has really been syphilitic.

The relation of inherited syphilis to idiocy appears to be a close one. What rôle the diathesis has in the production of those cases which are dependent upon arrest of development we have no way at present of knowing, but that it very frequently causes chronic hydrocephalus seems to be well established. A number of cases have been reported; they have been collected by Dr. E. Mendel, "Archiv f. Psychiatrie," Bd. i, 309. For a very important paper, see, also, Virchow's "Archiv," Bd. xxxviii, p. 129.

Nervous diseases following acquired syphilitic infection certainly belong to the advanced stages of the disorder. Huebner reports (von Ziemssen's "Cyclopædia," xii, 298, New York edition) a case in which thirty years elapsed between the contraction of the chancre and the nervous explosion. I have seen a similar period of thirty years. Fournier reports intervals of twenty-five years, and thinks from the third to the tenth year is the period of maximum frequency of nerve accidents.

The fact that cerebral syphilis may occur many years after the cessation of all evidence of the diathesis is one of great practical importance, especially when taken in conjunction with the circumstance that the nervous system is more prone to be attacked when the secondaries have been very light than when the earlier manifestations have been severe. I have repeatedly seen nerve syphilis in persons whose secondaries have been so slight as to have been entirely overlooked or forgotten, and who honestly asserted that they never had had syphilis, although they acknowledged to gonorrhœa or to repeated exposure, and confessed that their asserted exemption was due to good fortune rather than chastity.

To show that my experience is not peculiar, I may be allowed to make the following citations: Dr. Dowse ("The Brain and its Diseases," London, 1879, vol. i, p. 7) says: "Often have I had patients totally ignorant of having at any time acquired or experienced the signs or symptoms of syphilis in its primary and secondary stages, yet the sequelæ have been made manifest in many ways, particularly in many of the obscure diseases of the nervous system." Dr. Buzzard ("Syphilitic Nervous Affections," London, 1874, p. 80) reports a case of nervous syphilis where the patient was unconscious of the previous existence of a chancre or of any secondaries. Professor Rinecker also calls attention ("Archiv f. Psychiatrie," vii, p. 241) to the frequency of nervous syphilis in persons who afford no distinct history of secondary symptoms.

This frequent absence of history of specific infection is of great practical importance, and has led me to attach comparatively little weight to the statements of patients. In private practice I usually avoid asking questions which might bring up from the past unpleasant memories, and arrive at the diagnosis by studying the symptoms present.

Although syphilis is most prone to attack the nervous system many years after infection, it would be a fatal mistake to suppose that brain disease may not rapidly follow the occurrence of a chancre. What is the minimum possible intermediate period we do not know, but it is certainly very brief, as is shown by the following cases of this so-called precocious cerebral syphilis: Dr. Alfrik Ljunggrén, of Stockholm, reports ("Archiv f. Dermatol. und Syphilis," 1870, ii, p. 155) the case of H. R., who had a rapidly healed chancre in March, followed in May of the same year by a severe headache, mental confusion, and giddiness. Early in July H. R. had an epileptic attack, but he was finally cured by active anti-syphilitic treatment. Although the history is not explicit, the nervous symptoms appear to have preceded the development of distinct secondaries other than rheumatic pains.

Davaïne is said (Buzzard, "Syphilitic Nervous Affections," London, 1874) to have seen paralysis of the portio dura "a month after the first symptoms of constitutional syphilis." Dr. E. Leyden ("Zeitschrift f. klin. Med.," Bd. v, 165) found advanced specific degeneration of the cerebral arteries in a man who had contracted syphilis one year previously. Dr. R. W. Taylor details a case in which epilepsy occurred five months after the infection ("Jour. of Nervous and Mental Dis.," 1876, p. 38). In the case of M. X., reported by Dr. Ad. Schwarz ("De l'hémiplegie syphilitique précoce," Inaug. Diss., Paris, 1880), headache came on the fortieth day after the appearance of the primary sore, and a hemiplegia upon the forty-sixth day. S. L. (*Ibid.*) had a paralytic stroke, without prodromes, six months after the chancre. A. P. L. (*Ibid.*) had an apoplectic attack seven months after the chancre; A. S., one five months after her chancre. In a case which recently occurred in the practice of Dr. A. Sydney Roberts, of this city, the chancre appeared after a period of incubation of twenty-six days, and two months and eight days subsequent to this came the first fit; eight days after the first the second convulsion occurred, with a distinct aura, which preceded by some minutes the unconsciousness. The further details of this case are not germane to the present discussion, which only requires the additional statement that the attack developed into an unmistakable cerebral syphilis with temporary aphasia, and that convalescence was finally secured by active anti-syphilitic treatment. As the first paroxysm came on without warning, while the man was fishing in the sun, it is not unwarrantable to suppose that a precocious cerebral syphilis was in this case precipitated by exposure to the ordinary causes of sunstroke. This list of cases might be much extended, but it certainly is sufficient to show that cerebral syphilis occurs not very rarely within six months after infection, and may be present in two months.

An interesting observation in this connection is that of Dr. Ern. Gaucher ("Revue de méd.," 1882, ii, 678) of a spinal syphilis occurring six months after the appearance of a chancre.

Syphilographers are in accord in regard to the existence of two pathological varieties of brain syphilis, while some authorities believe in a third form. The most common seat of attack is the membranes; next to these are the brain-vessels; while, as already intimated, there is difference of opinion as to whether the disease ever directly affects the brain-tissue. Reasons will be given later on for believing that the brain-substance may suffer violence from syphilis, but I shall first discuss the clinical aspects of specific disease of the membranes.

Disease of Brain Membranes.—Specific affections of the brain membranes very often declare themselves with great suddenness. The records of the disease present case after case in which an apoplectic attack, a convulsive paroxysm, a violent mania, or a paralytic stroke has been the first detected evidence

of syphilitic cerebral disease. On the other hand, in many instances the symptoms come on slowly and successively. Proper treatment, instituted at an early stage, is usually successful, so that a careful study of these prodromes is most important. They are generally such as denote cerebral disturbance; and, although they should excite suspicion, are not diagnostic, except as occurring in connection with a specific history, or under suspicious circumstances.

Headache, slight failure of memory, unwonted slowness of speech, general lassitude, and especially lack of willingness to mental exertion, sleeplessness or excessive somnolence, attacks of momentary giddiness, vertiginous feelings when straining at stool, yelling, or in any way disturbing the cerebral circulation, alteration of disposition—any of these, and, *a fortiori*, several of them, occurring in a syphilitic subject, should be the immediate signal of alarm, and lead to the examination of the optic discs, for in some cases the eye-ground will be found altered even during the prodromic stage. Of course, if choked disc be found, the diagnosis becomes practically fixed, but the absence of choked disc is no proof that the patient is not suffering from cerebral syphilis. In regard to the individual prodromic symptoms, my own experience does not lend especial importance to any one of them, although, perhaps, headache is most common. There is one symptom which may occur during the prodromic stage of cerebral syphilis, but is more frequent at a later stage—a symptom which is not absolutely characteristic of the disease, but which, when it occurs in a person who is not hysterical, should give rise to the strongest suspicion. I refer to the occurrence of repeated, partial, passing palsies. A momentary weakness of one arm, a slight drawing of the face, disappearing in a few hours, a temporary dragging of the toe, a partial aphasia which appears and disappears, a squint which to-morrow leaves no trace, may be due to a non-specific brain tumor, to miliary cerebral aneurysms, or to some other non-specific affection; but, in the great majority of cases where such phenomena occur repeatedly, the patient is suffering from syphilis or hysteria.

The first type or variety of the fully formed syphilitic meningeal disease to which attention is here directed is that of an *acute meningitis*. I am much inclined to doubt whether an acute syphilitic meningitis can ever develop as a primary lesion; whether it must not always be preceded by a chronic meningitis or by the formation of a gummatous tumor; but it is very certain that acute meningitis may develop when there have been no apparent symptoms, and may, therefore, seem to be abrupt in its onset. Some years ago I saw, in consultation, a man who, in the midst of apparent health, was attacked by violent meningeal convulsions, with distinct evidences of acute meningitis. He was apparently saved from death by very heroic venesection, but, after his return to consciousness, developed very rapidly a partial hemiplegia, showing that a latent gumma had probably preceded the acute attack. On the other hand, an acute attack is liable at any time to supervene upon a chronic syphilitic meningitis. At the University Hospital Dispensary I once diagnosed chronic cerebral syphilis in a patient who the next day was seized with violent delirium, with convulsions and typical evidences of acute meningitis, and died four or five days afterward. At the autopsy an acute meningitis was found to have been ingrafted on a chronic specific lesion of a similar character. In the case reported by Dr. Gamel ("Tumeurs gommeuses du cerveau," Inaug. Diss., Montpellier, 1875), in which intense headache, fever, and delirium came on abruptly in an old syphilitic subject and ended in general palsy and death, the symptoms were found to depend upon an acute meningitis, secondary to a large gumma.

In this connection may well be cited the observation of Dr. Molinier ("Revue méd. de Toulouse," xiv, 1880, 341), in which

violent delirium, convulsions, and coma occurred suddenly. A very curious case is reported by Dr. D. A. Zambaco ("Des affections nerveuses syphilitiques, Paris, 1862, p. 485), in which attacks simulating those of acute meningitis appear to have been produced in a man with a cerebral gummatous tumor by a malarial complication. In such a case the diagnosis of a malarial paroxysm could only be made by the presence of the cold stage, the transient nature of the attack, its going off with a sweat, its periodical recurrence, and the therapeutic effect on it of quinine.

In the cases of *chronic meningeal syphilis* which have come under my observation, most usually after a greater or less continuance of prodromes such as have been mentioned, epileptic attacks have occurred with a hemiplegia, or a monoplegia, which is almost invariably incomplete and usually progressive; very frequently diplopia is manifested before the epilepsy, and, on careful examination, is found to be due to weakness of some of the ocular muscles. Not rarely oculo-motor palsy is an early and pronounced symptom, and a marked paralytic squint is very common. Along with the development of these symptoms there is almost always distinct failure of the general health and progressive intellectual deterioration, as shown by loss of memory, failure of the power to fix the attention, mental bewilderment, and, perhaps, aphasia. If the case convalesces under treatment, the amelioration is gradual, the patient traveling slowly up the road he has come down. If the case end fatally, it is usually by a gradual sinking into complete nerve-paralysis, or the patient is carried off by an acute inflammatory exacerbation, or, as I saw in one case, amelioration may be rapidly occurring, and a very violent epileptic fit produce a sudden asphyxia. In this form of cerebral syphilis death from brain softening around the tumor is not infrequent; but a fatal apoplectic hæmorrhage is rare.

The clinical varieties of cerebral meningeal syphilis are so polymorphic and kaleidoscopic that it is almost impossible to reduce them to order for descriptive purposes. Professor Fournier separates them into the cephalic, congestive, epileptic, aphasic, mental, and paralytic, but scarcely facilitates description by so doing. Heubner makes the following types:

"1. Psychological disturbances, with epilepsy, incomplete paralysis (seldom of the cranial nerves), and a final comatose condition, usually of short duration.

"2. Genuine apoplectic attacks, with succeeding hemiplegia, in connection with peculiar somnolent conditions, occurring in often-repeated episodes; frequently phenomena of unilateral irritation, and generally at the same time paralysis of the cerebral nerves.

"3. Course of the cerebral disease similar to paralytica dementia."

In regard to these types, the latter seems to me clear and well defined, but contains those cases which I shall discuss under the head of cortical disease.

Meningeal syphilis, as seen in this country, does not conform rigidly with the other asserted types, although there is this much of agreement that, when the epilepsy is pronounced, the basal cranial nerves are not usually paralyzed, the reason of this being that epilepsy is especially produced when the gummatous change is in the ventricles or on the upper cortex. In basal affections, the epileptoid spells, if they occur at all, are usually of the form of petit mal; but this rule is general, not absolute. The apoplectic somnolent form of cerebral syphilis, for some reason, is rare in this city; and it seems necessary to add to those of Professor Heubner a fourth type, to which a large proportion of our cases conform. This type I would characterize as follows:

4. Psychological disturbance without complete epileptic convul-

sions, associated with palsy of the basal nerves and often with partial hemiplegia.

The most satisfactory way of approaching this subject is, however, to study the important symptoms in severalty, rather than to attempt to group them so as to make typical, recognizable varieties of the disease, and this method I shall here adopt.

Headache is the most constant and usually the earliest symptom of meningeal syphilis; but it may be absent, especially when the lesion is located in the reflexions of the meninges, which dip into the ventricles, or when the basal gumma is small and not surrounded with much inflammation. The length of time it may continue without the development of other distinct symptoms is remarkable. In one case (Book Y, p. 88, 1879), at the University Dispensary, the patient affirmed that he had had it for four years before other causes of complaint appeared. It sometimes disappears when other manifestations develop. It varies almost indefinitely in its type, but is, except in very rare cases, at least so far paroxysmal as to be subject to pronounced exacerbations. In most instances it is entirely paroxysmal; and a curious circumstance is that very often these paroxysms may occur only at long intervals; such distant paroxysms are usually very severe, and are often accompanied by dizziness, sick stomach, partial unconsciousness, or even by more marked congestive symptoms. The pain may seem to fill the whole cranium, may be located in a cerebral region, or fixed in a very limited spot. Heubner asserts that when this headache can be localized it is generally made distinctly worse by pressure at certain points, but my own experience is hardly in accord with this. Any such soreness plainly can not directly depend upon the cerebral lesion, but must be a reflex phenomenon, or due to a neuritis. According to my own experience, localized soreness indicates an affection of the bone or of its periosteum. In many cases, especially when the headache is persistent, there are distinct nocturnal exacerbations.

It will be seen that there is nothing absolutely characteristic in the headache of cerebral syphilis; but excessive persistency, apparent causelessness, and a tendency to nocturnal exacerbation should in any cephalalgia excite suspicion of a specific origin—a suspicion which is always to be increased by the occurrence of slight spells of giddiness, or by delirious mental wandering accompanying the paroxysms of pain. When an acute inflammatory attack supervenes upon a specific meningeal disease, it is usually ushered in by a headache of intolerable severity.

When the headache in any case is habitually very constant and severe, the disease is probably in the dura mater or periosteum, and this probability is much increased if the pain be local and augmented by firm, hard pressure upon the skull over the seat of the pain.

Disorders of Sleep.—There are two antagonistic disorders of sleep, either of which may occur in cerebral syphilis, but which have only been present in a small proportion of the cases that I have seen. Insomnia is more apt to be troublesome in the prodromic than in the later stages, and is only of significance when combined with other more characteristic symptoms. A peculiar somnolence is of much more determinate import. This may occur in non-specific lepto-meningitis, and in states of altered brain nutrition from senile or other degenerations of the walls of the cerebral vessels, and is, therefore, not pathognomonic of cerebral syphilis, yet, of all the single phenomena of the latter disease, it is the most characteristic. Its absence is of no import in the theory of an individual case.

As I have seen it, it occurs in two forms: In the one variety the patient sits all day long or lies in bed in a state of semistupor, indifferent to everything, but capable of being aroused, answering questions slowly, imperfectly, and without complaint,

but in an instant dropping off again into his quietude. In the other variety the sufferer may still be able to work, but often falls asleep while at his tasks, and especially toward evening has an irresistible desire to slumber, which leads him to pass, it may be, half of his time in sleep. This state of partial sleep may precede that of the more continuous stupor, or may pass off when an attack of hemiplegia seems to divert the symptoms. The mental phenomena in the more severe cases of somnolency are peculiar. The patient can be aroused; indeed, in many instances he exists in a state of torpor rather than of sleep; when stirred up, he thinks with extreme slowness, and may appear to have a form of aphasia, yet at intervals he may be endowed with a peculiar automatic activity, especially at night. Getting out of bed; wandering aimlessly and seemingly without knowledge of where he is and unable to find his own bed; passing his excretions in a corner of the room, or in other similar place, not because he is unable to control his bladder and bowels, but because he believes that he is in a proper place for such act—he seems a restless automaton rather than a man.

Apathy and indifference are the characteristics of this state, and yet the patient will sometimes show excessive irritability when aroused, and will at other periods complain bitterly of pain in his head, or will groan as though suffering severely in the midst of his stupor, at a time too when he is not able to recognize the seat of the pain. I have seen a man, with a vacant, apathetic face, almost complete aphasia, persistent heaviness and stupor, arouse himself when the stir in the ward told him that the attending physician was present, and come forward in a dazed, highly pathetic manner, by signs and broken utterance begging for something to relieve his head. Heubner speaks of cases in which the irritability was such that the patient fought vigorously when aroused; this I have not seen.

This somnolent condition may last many weeks. Dr. T. Buzzard ("Clinical Lectures on Dis. of the Nerv. Syst.," London, 1882) details the case of a man who, after a specific hemiplegia, lay silent and somnolent for a month, and yet finally recovered so completely as to win a rowing match on the Thames.

In its excessive development, syphilitic stupor puts on the symptoms of advanced brain softening, to which it is indeed often due. Of the two cases with fatal result of which I have notes, one at the autopsy was found to have symmetrical purulent breaking down of the anterior cerebral lobes; the other, softening of the right frontal and temporal lobes due to the pressure of a gummatous tumor, and ending in a fatal apoplexy.

This close connection with cerebral softening explains the clinical fact that apoplectic hæmorrhage is very apt to end the life in these cases of somnolent syphilis. Dr. Buzzard's case given above, and others which might be cited, prove, however, that a prolonged deep stupor in persons suffering from cerebral syphilis does not prove the existence of extensive brain softening, and is not incompatible with subsequent complete recovery. As an element of prognosis, it is of serious but not of fatal import.

Paralysis.—When it is remembered that a syphilitic exudation may appear at almost any position in the brain, that spots of encephalic softening are a not rare result of the infection, that syphilitic disease is a common cause of cerebral hæmorrhage, it is plain that a specific palsy may be of any conceivable variety, and affect either the sensory, motor, or intellectual sphere. The mode of onset is as various as the character of the palsy. The attack may be instantaneous, sudden, or gradual. The gradual development of the syphilitic gumma would lead us, *a priori*, to expect an equally gradual development of the palsy; but experience shows that in a large proportion of the cases the palsy develops suddenly, with or without the occurrence of an apoplectic or epileptic fit. Under these circumstances it will be

usually noted that the resulting palsy is incomplete; in rare instances it may be at its worst when the patient awakes from the apoplectic seizure, but mostly it progressively increases for a few hours, and then becomes stationary. These sudden partial palsies probably result from an intense congestion around the seat of disease, or from stoppage of the circulation in the same locality; but, whatever their mechanism may be, it is important to distinguish them from palsies which are due to hæmorrhage. I believe this can usually be done by noting the degree of paralysis.

A suddenly developed, *complete* hemiplegia, or other paralysis, may be considered as in all probability either hæmorrhagic or produced by a thrombus so large that the results will be disorganization of the brain substance, and a future no more hopeful than that of a clot. On the other hand, an *incomplete* palsy may be rationally believed to be due to pressure or other removable cause, and this belief is much strengthened by a gradual development. The bearing of these facts upon prognosis it is scarcely necessary to point out.

Although the gumma may develop at almost any point, they especially affect the base of the brain, and are prone to involve the nerves which issue from it. Morbid exudations, not tubercular nor syphilitic, are very rare in this region. Hence a rapidly but not abruptly appearing strabismus, ptosis, dilated pupil, or any paralytic eye symptom in the adult, is usually of syphilitic nature. Syphilitic facial palsy is not so frequent, while paralysis of the nerve from rheumatic and other inflammation within its bony canal are very common. Paralysis of the facial may therefore be specific, but it is of no diagnostic value. Since syphilitic palsies about the head are in most instances due to pressure upon the nerve trunks, the electrical reactions of degeneration are present in the affected muscles.

There is one peculiarity about specific palsies which has already been alluded to as frequently present, namely, a temporary, transient, fugitive, varying character and seat. Thus an arm may be weak to-day, strong to-morrow, and the next day feeble again, or the recovered arm may retain its power, and a leg fail in its stead. These transient palsies are much more apt to involve large than small brain territories. The explanation of their largeness, fugitiveness, and incompleteness is that they are not directly due to clots or other structural changes, but to congestions of the brain tissues in the neighborhood of gummatous exudations. It is easily seen why a squint will remain when the accompanying monoplegia disappears.

Motor palsies are more frequent than sensory affections in syphilis, but hemianæsthesia, localized anæsthetic tracts, indeed, any form of sensory paralysis, may occur. Numbness, formications, all varieties of paræsthesia, are frequently felt in the face, body, or extremities. Violent peripheral neuralgic pains are rare, and generally, when present, denote neuritis. Professor Huguénin, however, reports ("Schweiz. Corr.-Blatt," 1875) a case in which a severe trigeminal anæsthesia dolorosa had existed during life as the only cerebral symptom, and, death occurring from lung disease, a small gumma was found on the sella turcica pressing upon the Gasserian ganglion.

The special senses are liable to suffer from the invasion of their territories by cerebral syphilis, and the resulting palsies follow courses and have clinical histories parallel to those of the motor sphere. The onset may be sudden or gradual, the result temporary or permanent. Dr. Charles Mauriac (*loc. cit.*, p. 31) reports a case in which the patient was frequently seized with sudden attacks of severe frontal pain and complete blindness, lasting from a quarter to half an hour; at other times the same patient had spells of aphasia lasting only for one or two minutes. In a case still under my care with unmistakable signs of cerebral syphilis, the man was suddenly and unaccountably seized

with complete deafness, which, after some days, disappeared in the course of a few hours. Like other syphilitic palsies, therefore, paralyses of special senses may come on suddenly or gradually, and may occur paroxysmally.

Among the palsies of cerebral syphilis must be ranked aphasia. An examination of recorded cases shows that it is subject to vagaries and laws similar to those connected with other specific cerebral palsies. It is usually a symptom of advanced disease, but may certainly develop as one of the first evidences of cerebral syphilis.

Coming on after an apoplectic or epileptic fit, it may be complete or incomplete; owing to the smallness of the center involved, and the ease with which its function is held in abeyance, a total loss of word thought is not so decisive as to the existence of cerebral hæmorrhage as is a total motor palsy. Like hemiplegia or monoplegia, specific aphasia is sometimes transitory and paroxysmal. Dr. Buzzard (*loc. cit.*, p. 81) records several such cases. Dr. Charles Mauriac ("Aphasie et hémiplegie droite syphilitique," Paris, 1877) details a very curious case in which a patient, after long suffering from headache, was seized by sudden loss of power in the right hand and fingers, lasting about ten minutes only, but recurring many times a day. After this had continued some time, the paroxysms became more completely paralytic, and were accompanied by loss of power of finding words, the height of the crises in the palsy and aphasia being simultaneously reached. For a whole month these attacks occurred five or six times a day, without other symptoms except headache, and then the patient became persistently paralytic and aphasic, but finally recovered.

To describe the different forms of specific aphasia and their mechanism of production would be to enter upon a discussion of aphasia itself, a discussion out of place here. Suffice to say that every conceivable form of the disorder may be induced by syphilis.

Owing to the centers of speech being situated in the cortical portion of the brain, aphasia in cerebral syphilis is very frequently associated with epilepsy. Of course, right-sided palsy and aphasia are united in syphilitic as in other disorders. If, however, the statistics given by M. Tanowsky ("L'aphasie syphilitique") be reliable, syphilitic aphasia is associated with left-sided hemiplegia in a most extraordinarily large proportion. Thus, in fifty-three cases collected by M. Tanowsky, eighteen times was there right-sided hemiplegia and fourteen times left-sided hemiplegia, the other cases being not at all hemiplegic. Judging from the autopsy on a case reported in Mauriac's brochure, this concurrence of left-sided paralysis and aphasia depends partly upon the great frequency of multiple brain lesions in syphilis, and partly upon the habitual involvement of large territories of the gray matter secondarily to diseased membrane. An important practical deduction is that the conjoint existence of left hemiplegia and aphasia is almost diagnostic of cerebral syphilis.

Probably among the palsies may be considered the disturbances of the renal functions, which are rarely met with in cerebral syphilis, and which are probably usually dependent upon the specific exudation pressing upon the vaso-motor centers in the medulla. Fournier speaks of having notes of six cases in which polyuria, with its accompaniment, polydipsia, was present, and details a case in which the specific growth was found in the floor of the fourth ventricle. Cases have been reported in which true saccharine diabetes has been present (consult Servantié, "Des rapports du diabète et de la syphilis. Paris Thèse, 1876), and I can add to these an observation of my own. The symptoms, which occurred in a man of middle age, with a distinct specific history, were headache, nearly complete hemiplegia, and mental failure, associated with the passage of com-

paratively small quantities of a urine so highly saccharine as to be really a sirup. Under the influence of the iodide of potassium, the sugar, in a few weeks, disappeared from the urine.

(To be concluded.)

New Inbentions, etc.

A BOW-LEG APPARATUS FOR DAY AND NIGHT USE.

THE cumbersome and unsightly apparatus usually employed in the treatment of bow-legs is so well known that no particular description of it is necessary, except by way of contrast with a recently devised apparatus, intended to be worn by day and during the night. The one commonly used consists of two upright bars of steel, jointed at the knee and ankle, connected at their lower end by means of a stirrup which is fastened to the shank of a shoe, usually made for the purpose, and having a leather-covered steel band which encircles the thigh just above, and another band just below, the knee. To the inner upright, at a point opposite the greatest convexity of the tibia, is fastened an elastic or inelastic band which passes around the leg, and, when properly adjusted, tends to draw the tibia inward toward the upright bar, whose bearings, by means of pads, are the inner condyle of the femur and the internal malleolus. The external upright bar serves only to steady the thigh and leg-bands, and adds to the unsightly appearance of the apparatus as well as to its weight. This can only be worn outside the stocking and during the day, it being necessary, from its construction, to have it secured by rivets to the shank of a stout shoe.

The accompanying cut is of an apparatus devised by Mr. W. F. Ford (of Caswell, Hazard & Co.), being a modification of the single-bar apparatus usually made by him, and of Fraser's bow-leg night-splint.

As will be seen by the cut, it consists of a single straight bar, having at its extremities broad pads, one of which rests on the head of the tibia and the other on the internal malleolus. A steel, leather-covered band secures the bar firmly at the top, and an elastic band keeps the lower end in place. Another elastic band, fastened to the center of the bar, passes around the leg and counteracts the tendency to the outward bowing of the bones. A slot in the upper end of the bar admits of shortening or lengthening the apparatus.

The obvious advantages of this form are lightness, the absence of joints, the non-necessity for its attachment to a shoe, and the fact that it can be worn under the stocking and during the night. To the latter feature is due the marked success attending its use; for, when the child is in a recumbent posture and the legs are relieved of the weight of the body, the yielding bones can be acted upon to much better advantage by the elastic band than when the child is running about.

Dr. B. D. Carpenter, of Jersey City, has given the apparatus a thorough test, and has found it more efficient than the other form and entirely free from the discomfort and other objectionable features of such appliances.

Miscellany.

THERAPEUTICAL NOTES.—*Phenic Acid in the Treatment of Typhoid Fever.*—Dr. F. W. Warvinge ("Nordiskt medicinskt Arkiv," xv, 16, 1883), in the course of an elaborate article on the antiseptic treatment of

infectious diseases, and particularly typhoid fever, states that he began treating the latter disease with phenic acid in 1881, and continued his experiments on a larger scale in 1882, treating fifty-four cases. While these trials do not warrant him in concluding that the drug is the most suitable antiseptic in this affection, they are such as to encourage further experimentation. He generally gives the medicine by the mouth, but also, and not uncommonly, in enemata. In either case, the common dose for adults is fifty centigrammes twice a day. The effects are not modified by the method of administration. A rapid fall of temperature always takes place, but it rises again after a few hours. Most of the patients felt comparatively well during the remission produced by the drug; abundant perspiration almost invariably occurred; the tongue remained moist during the continuance of the medication; the diarrhoea was usually diminished; the appetite was often restored early; the apathetic state was promptly ameliorated; the urine was less frequently albuminous than is generally seen in typhoid fever, and albuminuria was absent in many of the cases of carbouluria; and the course of the disease seemed to be mitigated and slightly abridged by the treatment. Three cases were fatal (being 5.5 per cent. against 11.5 per cent. of those treated on the expectant plan—the latter, too, including the more benign cases); and, in two of the fatal cases, grave complications arose after convalescence had begun, viz., gangrenous parotiditis and perforative peritonitis, while in the third case the patient's condition was miserable in every respect when the treatment was begun.

In spite of the decided antithermic action of phenic acid, the author does not consider this to be its most valuable property, but rather its powerful antiseptic effect, which, he thinks, must be exerted to some extent even in the organism, neutralizing the virus for the time being, arresting its reproduction, and thus aiding the *vis medicatrix nature* in its efforts at elimination—a view that is favored, he remarks, by the fact that the drug produces no effect on the temperature in persons who are free from fever.

The Administration of Paraldehyde.—At a recent meeting of the Paris *Société de Thérapeutique* M. Yvon stated ("Progrès médical," February 2, 1884) that paraldehyde was soluble in alcohol, in glycerin, in ether, and in water, and more soluble in these liquids when cold than when warm; also that it was soluble in water in the proportion of one part to two by weight. He gave the following two formulæ for disguising its taste:

Paraldehyde.....	20 grammes;
Alcohol (90°).....	100 "
Syrup.....	75 "
Tincture of vanilla.....	5 "

Ten grammes of this mixture contain one gramme of paraldehyde, and the mixture is given in doses of twenty to thirty grammes. It may also be prescribed as follows:

Paraldehyde.....	1 to 4 grammes;
Boiled water.....	30 "
Syrup.....	70 "
Tincture of vanilla.....	q. s.

The whole to be taken at once.

THE GOVERNMENT CONTROL OF THE UNITED STATES PHARMACOPEIA.—The February number of the "North Carolina Medical Journal" contains the following vigorous editorial:

A bill has been introduced into the House of Representatives by Mr. Randall, of Pennsylvania, to prepare and publish a national pharmacopœia. The chief of the Marine-Hospital Service, of the Navy, and of the Army, are each to detail two medical officers, and these officers are to invite the American Medical Association and the American Pharmaceutical Association to form committees of not more than three members, and, thus constituted, this board shall proceed to the work of forming a new pharmacopœia, said board having the power to add to its number from time to time as may in its judgment be necessary. Five thousand dollars are to be appropriated for carrying out the work.

No doubt this proposition will strike the profession in this country with surprise, more especially when the history of the pharmacopœia is recalled. From the beginning the labor and expense of the production of this work have been undertaken and carried forward by private

enterprise. The few men who have been interested in it have given their time and labor with an ardor which does credit to the two professions from which they came. Furthermore, they had the wisdom to keep this work alive by their desire to promote the best interest of the profession, and we are quite sure that none would have resisted quicker than they any movement, even by implication, which would have surrendered the work to the general Government. This is more than ever inferable when we remember that in the early conventions the organization was completed before the officers of the army and navy were invited to take seats.

It will be surprising, therefore, to the profession that there should have suddenly arisen an emergency which makes it now more necessary that "a national authoritative standard" should be undertaken by the Government.

The "Medical News," it seems, is able to give a reason. In its issue of February 9th it says: "Unfortunately, since 1880 the United States Pharmacopœia has become a matter of commercial speculation. While a vast amount of intelligent and well-directed labor was bestowed upon it by the Committee of Revision, taken as a whole it is by no means creditable to the science of the country, and complaints as to its inaccuracy and the inconvenience of its methods have been numerous. Not only was it thus inferior to former revisions, but it was padded out into an absurdly large and clumsy volume, and supplied to the profession at an extravagant price wholly disproportionate to its former rate. That this departure from the time-honored course followed in former revisions should awaken wide-spread dissatisfaction was inevitable; and it was to be anticipated that the dissatisfaction would lead the Government to supply a want which had always existed, but which had never before become so imperative as now."

Per contra, we consider it rather fortunate that the committee has been able to produce a volume that could attain to any sort of commercial dignity, instead of preparing revision after revision that did not possess any. We can not agree, either, that the revision was supplied at an extravagant price, for, had this been so, the volume would not have been sought after so eagerly in the book market by such a large number of purchasers—a number far greater than for any previous edition, however cheap. The medical and pharmaceutical professions were willing to pay the price asked for the work, just as they would for anything they thought worth the money.

As to the inferiority of the present revision as compared with previous ones, we will let the "British Medical Journal," p. 700 (October, 1883) speak. The reviewer in that journal has been comparing the British Pharmacopœia, the German Pharmacopœia, and the United States Pharmacopœia (1880), and says: "In comparing the three pharmacopœias, it must at once be conceded that the United States Pharmacopœia is incomparably the best. The previous revision was very poor, but the present revision is a very great improvement on the last. It contains an enormous mass of information, which is, however, chiefly of use to the pharmacist. Nevertheless, it contains almost every possible preparation which can be needed by the medical practitioner."

We think the "Medical News" will be greatly disappointed in not finding "a professional approval" [of the proposed national pharmacopœia] "practically unanimous." Not a large number of men are going to give the matter a thought, if we are to judge by the past. But, of those who do actively consider the subject, we believe that very few will have such poor memories as to overlook the undesirable basis upon which, by the conditions of this bill, the national pharmacopœia would be founded. An expensive and disappointing experiment has already been tried by attempting to combine such incongruous bodies as the Army, Navy, and Marine-Hospital Service, and the result was the wrecking of the National Board of Health, through the ambition of the Marine-Hospital Service. With this disaster staring a confiding profession in the face, it is now proposed to reform the old combination, and to attach enough civilian experts to the board to give it a general scientific character, and so avoid the suspicion of making it a purely government work.

We think when these facts are duly considered, if the profession of medicine and pharmacy are to have any voice in the matter, they will more nearly unanimously reject the proposition.

Another point. The whole movement, as set forth first in the Ran-

dall bill, and in the approving editorial of the "Medical News," has too much of the color of rivalry between New York and Philadelphia not to be understood by non-residents of those favored cities. Some of the gentlemen of the latter city have never been able to disguise their dissatisfaction at the departure of the pharmacopœia from them, and we do not believe a word of complaint against the scientific part of the present revision of the pharmacopœia would have been sounded had the business management been to the liking of the complainants.

But we assert, even if the proposed plan is excellent in every respect, there is no reason why a new pharmacopœia should be compiled at an earlier date than 1890. We are willing to take the opinion of the "British Medical Journal" upon this subject, and repeat that the United States Pharmacopœia is incomparably the best in any language, and a wise Congress will not willingly interrupt the course of a scientific body, pursuing its work zealously and honestly, and at its own expense.

THE BRITISH MEDICAL ASSOCIATION; MEETING AT BELFAST.—The fifty-second annual meeting of the association will be held on July 29, 30, and 31, and August 1, 1884, at Belfast, under the presidency of James Cuming, M. A., M. D., F. R. C. S. P. I., Professor of Medicine, Queen's College, Belfast. The Address in Medicine will be delivered by Sir Andrew Clark, Bart., M. D., F. R. C. P., Physician and Lecturer on Clinical Medicine, London Hospital. The Address in Obstetric Medicine will be delivered by George H. Kidd, M. D., F. R. C. S. I., Master of the Coombe Lying-in Hospital, Dublin. The Address in Physiology will be delivered by Peter Redfern, M. D., F. R. C. S. E., Professor of Anatomy and Physiology, Queen's College, Belfast.

Visitors coming from America to attend this meeting can travel by any of the following routes:

1. A Cunard steamer will leave

(a) New York on Wednesday, July 16th, arriving in Queenstown about the following Thursday week, July 24th.

(b) Boston on Saturday, July 19th, reaching Queenstown the following Monday week, July 28th.

2. A White Star steamer will leave New York on Saturday, July 12th, and on Saturday, July 19th; due at Queenstown about July 20th and July 27th.

3. An Imman steamer will leave New York on Tuesday, July 15th; due at Queenstown about July 23d.

4. An Allan steamer will leave Quebec on Saturday, July 19th; arriving in Londonderry about the 26th or 28th of July.

5. An Anchor steamer will leave New York on Saturday, July 19th; due at Londonderry on July 29th.

Londonderry is 95 miles from Belfast, and trains run daily between the two places. The route from Queenstown to Belfast is from Queenstown to Cork, Cork to Dublin (165 miles by train), and Dublin to Belfast (113 miles).

Communications in reference to the meeting may be addressed to the honorary local secretaries, John Moore, M. D., Alex. Dempsey, M. D., John W. Byers, M. A., M. D.

THE INTERNATIONAL MEDICAL CONGRESS.—The time of the meeting of the British Medical Association at Belfast has been fixed so as not to interfere with the International Medical Congress, which is to begin at Copenhagen on August 10th. A steamer will leave Hull (England) on August 2d and 9th, for Copenhagen; and on August 6th a steamer will leave Leith (Scotland) for Copenhagen. Both these places (Hull and Leith) can be reached on any day by leaving Belfast on the previous evening by the cross-channel steamers. Visitors, after attending the meeting of the British Medical Association in Belfast, will have ample time to travel to Copenhagen for the congress.

THE INTELLIGENCE OF CORONERS' JURIES was aptly illustrated by the verdicts rendered in two cases of alleged poisoning which occurred recently in Ithaca, N. Y. Notwithstanding a chemical analysis revealed in the stomachs of both traces of an unrecognized poison, one, however, in a less degree than the other, the verdict rendered by the jury who investigated the worst case was: "Death from natural causes"; and, in the case which gave the least evidence of poison, death was found to have been caused by some poison unknown to the jury.

Original Communications.

THE FUNDAMENTAL PRINCIPLES OF
MECHANICO-THERAPY IN
HIP DISEASE.*

By MILTON JOSIAH ROBERTS, M.D.,

PROFESSOR OF ORTHOPÆDIC SURGERY AND MECHANICAL THERAPEUTICS IN
THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISIT-
ING ORTHOPÆDIC SURGEON TO THE CITY HOSPITALS ON RANDALL'S ISLAND;
PROFESSOR OF ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF VERMONT,
ETC.

UPON my arrival at the hospital of the New York Post-Graduate Medical School a few days since, I found among the out-patients awaiting me two with hip-joint disease. Both of them had been under treatment at my clinic for several months. When they first came under observation both were so crippled in consequence of the disease that locomotion was absolutely out of the question. To one, a short hip splint was applied; to the other, a long hip splint. Immediately thereafter and ever since these patients have been entirely free from untoward symptoms. The support rendered and force exerted by their respective splints at once relieved all pain and made locomotion not only possible, but comfortable. The consequence has been, that they have had the full privileges for play and out-of-door exercise which are ordinarily granted to healthy children.

The appliances worn by these patients were devised to carry out the mechanico-therapeutic indications which I considered to be present in their respective cases; the same, in fact, which I consider to be present in the vast majority of examples of this disease. These instruments were devised for the special purpose of securing the *maximum degree of protection to the diseased areas*, without confinement of the patient in bed. Upon examination, they will be found to be widely at variance with the forms of apparatus hitherto constructed for this purpose. Not only do these instruments differ in form from those hitherto used, but they are constructed to carry out therapeutic ideas of exactly opposite polarity from those generally taught in this country or in Europe—ideas which, as applied to the hip joint in a modified form, were first enunciated, I am proud to say, by our countryman Dr. Henry G. Davis more than twenty-five years ago. For want of satisfactory mechanical devices with which to carry them out, however, they have been almost forgotten. The facts, then, are these:

Two patients were before me who had been under mechanical treatment for hip disease for several months. They had been subjected to therapeutic measures the value of which will be denied by most living authorities. Yet, from the inception of treatment up to that time, they had steadily and surely progressed toward a recovery looking to the *permanent re-establishment of the function of the joint*. Nor had either of them at any time during the course of the treatment experienced undue discomfort or pain. Furthermore, the histories of the two cases referred to only serve to

illustrate the favorable results which have been obtained by the adoption of the same principles of treatment in many examples of analogous arthropathies.

Under these circumstances, it will be interesting to consider somewhat critically the various views which have been advanced regarding the principles of mechanical treatment in hip-joint disease.

Our information respecting the natural history of this malady and its principal clinical phenomena is in a very creditable condition, as the unanimity of professional testimony emphatically affirms.

When, however, we come to study the appearance of its therapeutic canopy, we find the vast dome occupied for the most part with catholician nebule. Chirurgical constellations are only here and there dimly visible, and their relations to the signs of the phylacteric zodiac are so uncertain and capriciously varying that we are almost dispirited with attempting to make a reliable chart of articular therapy, and our remedial cognition seems irrevocably veiled in the lurid light of mysticism.

In undertaking to apply the scientific method to the solution of the difficult question before us, we must bear in mind that, before we can go beyond appearances and intelligently undertake to bring harmony out of apparent discord, we must review and afterward critically consider the concrete phenomena upon which the therapeutics of hip disease have been based; otherwise, we can never hope to rise above the information afforded by our senses. Let us, then, proceed at once to a review of the

THERAPEUTIC IDEAS DERIVED FROM CLINICAL SOURCES.

*Fixation.**—Fixation, or so-called "rest" of joints affected with chronic inflammation, is deemed by the mass of the profession to be one of the prime objects, if not the prime object, to be attained in their treatment. As applied to hip disease, it is perhaps the most universally accepted indication for treatment of any procedure in the whole domain of orthopædic surgery. To all who are studying this side of human disabilities in a scientific spirit, one or all of the following questions will sooner or later present themselves to their minds:

Whence came and what was the nature of the evidence upon which this dictum of "fixation" of chronically inflamed joints has been so firmly established? Is it the slow outcome of the scientific study of the therapeutic indications in hip or other articular diseases? Is it the result of carefully planned, conducted, recorded, and subsequently studied experiments, either upon lower animals or upon human beings? Have sufficient clinical observations bear-

* It is misleading to a clear conception of the question before us to use the words "fixation," meaning immobilization of the joint, and "rest" in the physiological sense, as synonymous terms. By so doing, not only an unproved but a demonstrably false hypothesis is admitted to be true, and will be sure to confuse or deceive both teacher and pupil. Again, a very common and equally calamitous error is the use of the word "rest," meaning the circumstancing of a part or the whole of the body in a condition favorable to the restitution of overworked, exhausted, or diseased tissues, as synonymous with "rest," meaning permanence of position with respect to surrounding parts.

* Read, by courtesy of the Business Committee, before the Medical Society of the State of New York, February 6, 1884.

ing upon this point been made by competent persons, recorded, studied, apparent exceptions satisfactorily explained, and all discernible sources of error studiously avoided, to place this idea so high in the esteem of the profession? Or is it another example of the firm support which blind credulity often gives to authority and to the ideas of antiquity? Can it be that the frequent reiteration of this dictum, unaccompanied by rational explanation or scientific demonstration, has been a sufficient basis upon which to erect a firm professional belief? Have we formed our beliefs first upon the statement of authority, considered the clinical and other evidence afterward with our eyes shut, and then declared all the testimony in favor of our preconceived notions?

I do not raise these questions in regard to the doctrine of fixation of chronically inflamed joints for the purpose of creating a sensation, nor have they for their object the stimulation of therapeutic incredulity. But, where there are so many conflicting statements as to the merits and demerits of certain therapeutic procedures, it behooves all of us who are earnestly searching after the truth to critically interrogate every statement and demand something more than mere *assertion* before we enlist ourselves under the command of any authority.

I speak deliberately when I say we should demand something more than mere assertion; for, as members of a profession desirous of scientific advancement, we are at least entitled to an attempt at a rational explanation of therapeutic procedures, even though a satisfactory demonstration be not yet possible. That mere assertion is the favorite method of acquiring an audience and "explaining" (!) the *rationale* of the remedial measures advocated, the following quotations from high authorities, favoring the doctrine of "fixation" and selected from independent sources, will make manifest:

One author autocratically asserts that, "whatever may be the origin of hip-joint disease, the morbid state is kept up by movement of the joint." Neither preceding nor following this statement are to be found the data for its substantiation. Another asserts that "immobilization is indicated by every feature of the pathology as revealed in morbid specimens." Here again is a simple assertion, and unaccompanied by any explanation as to how it is that abolition of articular motion is such a potent factor in promoting reparative processes. A third author, on the ground of an extended personal experience and the occupancy of an authoritative professional position, seeks to convince his readers of the value of articular immobilization in hip disease solely by avowing it as his *belief* "that the closer one can come to securing perfect rest (fixation), the better the final result will be."

And so I might go on citing the *assertions* of authors advocating "fixation," and, so far as I have been able to learn, without finding in conjunction therewith sufficient reliable data upon which to found such a sweeping generalization. Now, while it is undoubtedly true that certain individuals possess an innate therapeutic genius, or are endowed with that still higher mental quality of being able to *divine* trustworthy remedial measures far in advance of ex-

isting knowledge, this fact does not relieve them from the responsibility of earnestly endeavoring to discover the *rationale* of such measures for the benefit of humanity and the enlightenment of their professional brethren. The mere assertion that fixation of the diseased articulation should be the guiding star to our therapeutic endeavors is simply an evasion of the question, not a solution of it.

For the purpose of getting at the reliability and probable origin of the accepted evidence in favor of fixation, let us suppose ourselves before an aggravated example of hip-joint disease, the patient having not yet been placed under treatment. As he poses in his little chair, on the lounge, or in his mother's lap before us, you will observe him making use of his unaffected lower extremity as a splint for its disabled fellow. He is sitting or lying with his feet crossed, the usual position being with the foot of the unaffected limb placed behind that of the diseased member. The common interpretation of this observation is that the child is instinctively trying to "fix" his diseased articulation so that no motion of it can take place. Approaching our little patient more closely, he evinces a marked degree of apprehensiveness in his facial expression and general demeanor. Especially is this the case if he has been subjected to repeated examinations for diagnostic or other purposes. The apprehension of the little sufferer may be so great that he will even cry out before he is touched; or, if he is old enough and possesses the requisite courage, he will warn you not to touch him. What is the explanation of all this? The child has found that the slightest jar or motion of the limb gives him increased pain. He tells us that this is so, and it requires no great observational powers to see that, under existing circumstances, he is right; for the merest disturbance of the limb at an unexpected moment will cause him to cry out with pain. Is there any conclusion more natural to arrive at than that motion of this articulation should be prevented? In the face of these observations, who has the courage to run the risk of being declared deficient in intelligence by asking for further proof of the truth of this conclusion? The history of articular therapy tells us that few indeed have possessed this courage, or at least thought it worth while to make the demand. Hence it is (no further adduction of evidence being called for) that the doctrine of "fixation" of chronically inflamed joints, based upon a so-called common-sense observation, without experiment and without demonstration, has arisen to the dignity in many quarters of being accepted as a therapeutic maxim.

Methods adopted to Fix the Hip Joint.—For the purpose of supplementing or replacing the supposed intended use of the unaffected limb as an immobilizing splint, and likewise the supposed retentive action of the reflexly contracting muscles, numerous means have been adopted to "fix" or immobilize the joint. These may be conveniently tabulated under two main heads:

I. The patient to maintain the horizontal decubitus.

1. Supine or prone recumbency:

a. Stationary; on an ordinary mattress or a special couch.

b. Portable; *le grand appareil*, wire cuirass, etc.

2. Recumbency and adaptable enveloping* (partial or complete) splints. Such splints pass unsegmented over the affected articulation, or are provided with an adjustable hinge opposite the joint. They are applied:

- a. *En masse*. Exs.: Leather, gutta-percha, felt, thinly sheeted metal, etc.
- b. *In lamina*. Exs.: Plaster-of-Paris, silicate of sodium, gum, starch, etc., in conjunction with cotton or other fabrics.

3. Simple recumbency (without enveloping splints) and linear traction. The traction is exerted by:

- a. Weight and pulley.
- b. Coiled metallic springs or vulcanized rubber cords.

4. Recumbency and non-enveloping† splints:

- a. Unsegmented. Ex.: Thomas's splint.
- b. Segmented. Ex.: Taylor's, Stillman's, etc.

II. The patient permitted to move from place to place.

1. Enveloping (partial or complete) splints:

- a. Unsegmented. Exs.: Plaster-of-Paris, gutta-percha, felt, etc.
- b. Segmented; with proximal and distal portions connected by an adjustable or non-adjustable joint. Ex.: Willard's hip splint.

2. Enveloping splints and crutches, or crutch and cane:

- a. Without high heel and sole on shoe of foot of unaffected side.
- b. With high heel and sole on shoe of foot of unaffected side.

3. Crutches, or crutch and cane, *without* enveloping or other hip splints:

- a. With leg on affected side secured flexed at or near a right angle with the thigh.
- b. With high shoe or pattern worn on foot of unaffected side.

4. Non-enveloping splints, shafts of metal or wood, and with or without adjustable or non-adjustable joints:

- a. With pelvic and femoral portions; single shaft along outer aspect of thigh to point above the knee.
- b. Pelvic portion and single shaft on outer aspect of limb to a point just above the external malleolus.
- c. Pelvic portion with external shaft to point under the foot.
- d. Trunkal portion and external femoral shaft to point above knee.
- e. Trunkal portion and lateral shaft to point above external malleolus, or under the foot.
- f. Cervico-trunkal portion and external shaft to point above or below the foot.
- g. Ischio-pelvic portions with external and internal shafts.
- h. Ischiatic portion with single internal shaft.

In concluding this enumeration of the various means which have been employed to "fix" the hip joint, it should

* All enveloping splints held in position, either by straps or roller bandages, probably owe their efficiency in overcoming reflex spasm more to circum-pelvic and circum-femoral compression, as will hereafter be explained, than to arresting motion of the joint.

† With this form of apparatus the limb is usually enveloped by a firmly applied roller bandage—an unrecognized though potent subduer of reflex muscular spasm.

be observed that, for the most part, the substances made use of have been rigid, or of a non-resilient nature. Hence the quality of the support rendered must be very unlike manual support.

*Extension (traction).**—I wish now to call your attention to another therapeutic idea which has gained a wide acceptance. I refer to extension, or, to use a better term, *traction*, in the line of the deformity. Though the majority of physicians throughout the civilized world implicitly pin their faith to the one idea of fixation, a large number advocate traction in conjunction with it. They have found that, by taking hold of the limb with their hands and supporting it as nearly as possible in one position, and making gentle traction in the line of the deformity, the patient derives increased comfort therefrom; and, furthermore, that the reflex muscular spasm is more quickly overcome than when no tractile force is exerted. So there has been added to the original idea of a "fixation" another one—that of traction ("extension").

Methods adopted for the Co-employment of Fixation and Traction.—To conjointly carry out the ideas of articular immobilization and linear traction by the use of a single instrument, it was necessary to construct an entirely new system of mechanical appliances adapted to the hip and other important joints of the body. Numerous and exceedingly ingenious have been the means adopted and the instruments constructed for the co-employment of these two ideas, and the degree of perfection attained in the construction of splints for this purpose within recent years, especially in America, shows how earnestly and devotedly the subject has been studied.

To fix and make traction on the joint, the maintenance of the horizontal decubitus, in conjunction with diversified forms of adaptable enveloping and non-enveloping splints, as well as nearly every conceivable form of portable splint, segmented and unsegmented, in conjunction with crutches, with or without a high shoe—all provided with the means of exerting interrupted or constant tractile force—has been brought into play. With one or two exceptions, however, all tractile hip-splints have been constructed so as to exert only *rigid* linear traction, which possess none of the resilient or elastic qualities of manual traction.

INQUIRY INTO THE THERAPEUTIC SIGNIFICANCE OF THE CLINICAL PHENOMENA DERIVED FROM AN EXAMINATION OF THE HIP-DISEASED PATIENT, AND THE REMEDIAL MEASURES BASED UPON THEM.

But now let us approach this hypothetical case in a little more critical frame of mind. Let us interrogate every observation, eliminate all discoverable sources of error, weigh every conclusion, and, if, after all this, the result is the same

* The use of the word *extension* to convey the idea of the linear application of force tending to lessen intra-articular pressure is, as has been pointed out by Yale, Judson, and others, open to the serious objection of being more frequently used to convey the idea of that movement of a joint which opposes flexion. On the contrary, the word *traction* conveys exactly the idea which we wish to express, and no other. It, however, should only be used as a generic term, as will hereafter appear, and should be preceded or followed by a word or words designating the quality and direction of the tractile force.

as before, we shall at least have performed our duty as scientific physicians by not having permitted ourselves to form beliefs on the basis of casual observation.

Regarding Fixation.—First, let us direct our attention to the idea of *fixation*. Remembering that

"Errors, like straws, upon the surface flow,"

let us have the courage to ask, Was it the purpose of the little patient, or did he succeed in "fixing" his diseased hip joint by making use of his unaffected limb as a splint? Were not his efforts directed simply to affording *support* to a disabled member rather than to fixing the joint? What significance shall we attach to the existence of reflex spasm of the skeletal muscles passing over the affected articulation? Is it, as is ordinarily affirmed, an effort on the part of Nature to arrest the movement of the joint? Or is this approximation to articular immobility the incidental result of the contraction of muscles in obedience to the supremacy of a physiological law?*

If I take hold of the limb, gently grasping the leg just below the knee with one hand, while with the other, placed upon the mid-posterior aspect of the thigh, I exert additional manual support, I shall find that my little patient is deriving considerable relief therefrom. He no longer manifests a marked degree of apprehension. The transverse and perpendicular furrowing of the forehead is almost obliterated and his facial expression less anxious. Is this result a confirmation of the value of fixing the diseased articulation? It only requires the asking of a second question to answer the first, viz.: Is it possible for *human hands* to hold an object in a "fixed" position? With our hands it is an easy matter to very effectually *support* the disabled member; but we can not exert a fixed or non-resilient force. A still greater augmentation of comfort on the part of the patient can be effected by making firm circumfemoral manual compression in conjunction with efficient support, thereby lessening myotic instability and reflex contractility.

Relief to our patient came, then, not from immobilization of the joint, for with human hands it is impossible to
